1. Introduction

All nonmetallic organic and inorganic materials are semiconductors. They provide a vastly greater resistance towards a flowing electric current than metallic conductors. Their resistivity may be 27 powers of ten greater than that of a conductor.

The differing electrical conduction behavior of conductors and semiconductors is a result of their atomic structure. In metallic conductors, the electric current results from the movement of free electrons. In contrast, the extremely small, but nevertheless existant conductivity of the so-called nonconductors arises from electrons and ions which migrate under the influence of electric fields. Since dissociation induced by cosmic radiation always generates a significant level of freely moving electrons and ions, an absolute nonconductor is not possible.

Within the field of electrotechnics, nonconductors (insulators) are generally employed to insulate the current-carrying components of conducting circuits from their surroundings. Insulators should prevent contact between conductors and energy losses caused by stray tracking currents. The function of insulators therefore is to prevent the undesirable flow of current between two conductors subjected to a potential difference. Insulators must possess a maximum electrical resistance under all the conditions to which the system can be exposed, e.g., at elevated temperature (electrothermal applications), at high voltages (energy technology), or high frequency (telecommunications). Insulation can be improved by appropriate design of the insulator. The choice of a suitable insulating material, however, remains critical for successful insulation. If insulating materials are used to fill the free space between the electrodes of capacitors,

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a14_321

then insulators act as dielectrics and have the additional function of storing electrical energy.

Not all materials of high resistivity (see Section 2.2) are suitable for use as electrical insulating materials. Additional chemical, mechanical, thermal, and, depending upon the application involved, further properties are required. Stability toward various electrical and nonelectrical influences [e.g., toward electrical discharges in cavities and at interfaces (see Section 2.8), toward heat produced by dielectric dissipation (see Section 2.5) and toward ignition and burning] is of major importance. The working life of an insulated electric circuit depends mainly upon the thermal aging behavior. Although a material may be technically suitable as an insulator, unfavorable processing properties or the manufacturing price can restrict its applications.

The selection of an insulating material lies in the hands of the designer, provided the properties necessary for the function in question are guaranteed. To ensure this, materials are tested according to national standards or IEC publications. The results of these tests permit comparison of the insulating materials under the specified conditions. Data for a specific material cannot generally be applied to an insulating component because the component and its insulation properties are influenced by design and manufacturing processes. The final decision regarding functionality must be made by testing the component itself.

Insulating materials can be subdivided into inorganic and organic materials. Inorganic insulators include natural products such as mica or asbestos. Synthetic insulators made of ceramics, glass, or more recently glass ceramics are of greater significance, however. Organic insulating materials are primarily synthetic polymers. All of these insulating materials have a secure position within the electrical industry, because of their special material properties or the efficient processes used to manufacture components from them. Developments have afforded new materials with improved properties. Developments within the electronics and electrical industries make the availability of new improved insulating materials essential

In their original form, natural materials are seldom able to meet the diverse requirements demanded of an electric insulating material; however, purification, preparation, or chemical modification, often increase their value. Polymers (thermoplasts, thermosets, and elastomers) are mainly synthetically manufactured products. Electric insulating materials are generally industrial products of complex chemical structure which have been adapted to suit their intended application by treatment, modification, and blending.

Compared with metallic conductors and magnetic substances, insulating materials represent the most comprehensive material group within the field of electrotechnics and possess the greatest number of technically interesting properties. Nonelectrical properties have been considered here only to an extent sufficient to permit a brief characterization.

Groups of organic insulating materials are listed in Chapter 3 according to their chemical composition. In most cases, organic products based on rubber or other polymers can be modified by processing. Hence an absolute value for a property of a given insulator group does not exist. For this reason, data are not presented in tabular form but as performance relief diagrams. The values shown in each block diagram merely indicate the range of the properties of main interest. Organic products which find application in the electrotechnics industry are generally employed with additives, which can often considerably influence electrical and dielectric properties. The most common additives include processing aids, stabilizers, pigments, fillers, and flame retardants.

2. Properties and Testing Methods

The electrical behavior of electrical insulating materials results from the physical processes of dissociation, polarization, and ionization.

Certain assumptions about the formation of free electrons and bound charge carriers under the influence of electrical fields are associated with these terms. They are responsible for electrical resistance, dielectric polarization, and electrical breakdown. In the broadest sense, these measurable parameters can be regarded as physical properties. Electrical insulating materials are materials with a resistivity $>10^6\,\Omega\cdot\mathrm{m}$ ($>10^8\,\Omega\cdot\mathrm{cm}$). The energy values which the electrons in a solid are able to assume can be

classified in an energy step scheme known as the "band model". Various energy levels exist:

1) energy levels which are occupied by electrons in the ground state of the atom;
2) energy levels which are accessible to electrons after introduction of energy (excited state); and
3) energy levels which cannot be occupied because of the Pauli exclusion principle.

The description of conducting processes in a solid material involves only the outermost electron-filled energy levels (the basic or valence band) and the next highest permissible energy range. In an insulating material, the valence band is completely filled with electrons, whereas the conduction band is empty. Following the introduction of energy, for example in the form of thermal energy, electrons are excited from the valence band and enter the conduction band. Here, they possess increased mobility and consequently lead to electrical conductance. In this way, an insulating material can attain a semiconductor character at elevated temperature.

In an insulating material, a prohibited energy zone occurs between the valence and conduction bands which is so large that an activation energy of >2 eV is required for an electron to make the transition. For this reason, practically no electrons occupy the conduction levels at room temperature.

Test procedures exist for reproducing or simulating technical conditions. The principles of these tests are often not evident, but can also be traced back to physical processes. The most important process in low-voltage technology is that used to determine resistance to tracking. Additionally, methods are used to determine promotion of corrosion, to observe electrostatic charging behavior, to investigate behavior towards partial discharges, and to assess the damage caused by arcing. Studies of thermally stimulated discharge currents provide further physical information [22].

2.1. Resistance to Tracking

Tracking is the progressive decomposition of the surface of a solid insulating material caused by local discharge and subsequent development of a conducting or partially conducting tracking path [23]. The international report of the International Electrotechnical Commission (IEC Publication 664/664 A) classifies insulation materials for low-voltage technology into four groups, according to their comparative tracking indices (CTI) [24]. The electric strength and the insulation resistance are disregarded, but they should be in a range appropriate for an insulating material.

Insulating material I:	CTI = 600
Insulating material II:	CTI = 400 – 575
Insulating material III a:	CTI = 175 – 375
Insulating material III b:	CTI = 100 – 150

Figure 1. Diagram for determining the comparative tracking index (CTI) according to ASTM D 3638/UL 764 A
Curves are shown for two materials of differing behavior but with a CTI of 325.

The international standard IEC Publication 112-1979 stipulates conditions for measuring

resistance to tracking. The United States standard ANSI/ASTM 3638-1977 [25] forms the basis for tests according to the testing regulations ANSI/UL 746 A-1984 [26]; these differ from the currently valid international standard (IEC Publication 112-1979) in the type of evaluation procedure employed and in the lack of opportunity for using a more aggressive testing solution (B).

During testing, surface contamination is simulated by allowing an appropriate test fluid to drip onto the surface. The IEC Publication 112 specifies five separate determinations of a.c. voltage (50 – 60 Hz) at which 50 drops of test solution between the platinum electrodes do not lead to failure. In contrast, ASTM 3638-1977 stipulates one measurement at a number of test voltages and comparison with a standard curve. The point of intersection of this curve with the 50-drop line is determined on the plot of droplet number as a function of the testing voltage; the test voltage is read off the abscissa (voltage axis) and the CTI is thus determined (Fig. 1).

Figure 2. Schematic representation of measurement of low-voltage tracking
a) Current limiting resistor; b) Excess current switch is activated by relay (c) when $I \geq 0.5$ A for 2 s; c) Relay; d) Contamination fluid; e) Platinum electrode; f) Specimen; g) Voltage supply

Test solution A comprises 1 g of ammonium chloride dissolved in 1 L of deionized water. The concentration of ammonium chloride in testing solution B is identical, but a specified amount of a given wetting agent is also added. The testing solutions therefore differ in their electrolytic conductivity because the wetting agent introduces almost the same contribution to the total conductivity as the ammonium chloride salt. The testing solutions also differ in their surface tension.

According to the definition given in the standards, a track has developed when the tracking current on the tracking path is greater than or equal to 0.5 A for at least 2 s, or when the specimen begins to burn as a result of the heat generated. A circuit used for evaluating tracking is shown in Figure 2.

The test is carried out at voltage steps between 100 and 600 V. The maximum test voltage which can be divided by 25 without a remainder represents the comparative tracking index CTI, provided that the test specimen (which must be at least 3 mm thick) can also withstand a further five tests with 100 drops at a voltage 25 V lower than the maximum value. Should a sample not fulfill this requirement, the voltage must be reduced in steps of 25 V and the value must be determined at which 100 drops can be withstood without failure. The magnitude of this voltage is given in parentheses following the CTI.

To avoid the incorrect characterization of strongly eroding materials, the standard recommends that the maximum depth of erosion from the five evaluated results of the tracking path formation is determined and indicated along with the CTI. This also applies when no tracking path is generated, e.g., due to sample ignition or when, although tracking paths are formed at a test voltage of 600 V, a current of 0.5 A is not exceeded.

2.2. Volume Resistivity

Volume resistance is obtained by dividing the d.c. voltage between two electrodes placed on two opposite faces of a specimen by the steady-state current between these electrodes. The volume resistivity ϱ is defined as the volume resistance relative to a cube with unit volume [27].

When a d.c. voltage is placed across two electrodes which are in intimate contact with a specimen (Fig. 3), the current passing through the sample decreases asymptotically towards a

constant end value. The drop in current can be caused by dielectric polarization and by migration of highly mobile ions toward the electrodes. The insulation resistance is generally determined 1 min after the beginning of the electrification.

Figure 3. Circuit diagram for measuring volume resistivity
a) Voltage supply; b) Switch; c) Voltmeter; d) Shielded ammeter; e) Specimen; f) Electrode

The current flowing along the surface, and the current arising from the polarization phenomena on the electrodes during careful and exact measurements must be excluded from the measurement. This is achieved by using appropriate circuits and measurement procedures.

Electrodes used for these tests are metal-like conductors or metallic conducting materials of suitable shape, size, and design; they are placed in intimate contact with the specimen and form the transition regions between the electron current and the ion-mediated current flow in the insulator. With liquid insulators, the electrodes are provided by the completely wetted container in which the measurements are being carried out (fluid electrode). With solid insulators, the electrodes must be adhered to the material (Fig. 4). Even under pressure, placing metallic components of dimensions stipulated in the standards on or beneath the sample material is not adequate in order to determine publishable results. None of the insulating materials has a perfectly flat surface. Therefore, in extreme cases, disk-shaped electrodes only make defective contact at three elevations on the sample surface.

The international standard testing process is specificied in IEC Publication 93 [27] for solid materials and IEC Publication 247 [28] for liquid insulators. Recommendations for measuring the insulation resistance at elevated temperature are given in IEC Publication 345 [29].

2.3. Surface Resistivity

The electrical insulation behavior of an insulator is influenced considerably by the nature of its surface, as well as by adsorbed or contamination layers. Conduction across the surface produced by these effects is known collectively as surface conductance. To decrease this property, the length of the conduction pathway can be increased, for example by mounting ribs or shielding on the insulator. The removal of contamination layers is simplified by using a smooth surface, which is achieved in ceramic insulating components by glazing.

The contribution of adsorbed and contamination layers to surface conduction illustrates that this parameter is not a material property. However, the deposition and enrichment of adsorbed

layers is also influenced by the nature and structure of the surface of the material. For example, in inorganic insulating materials the formation of adsorbed water layers is related to the phase characteristics of the surface: the polished surfaces of ceramic insulator components often exhibit a greater surface conductance than the fired, glass-enriched surface. A significant increase in surface conductance can be observed with increasing air humidity.

Surface resistance is obtained by dividing the d.c. voltage between two electrodes in contact with the surface of a sample by the current flowing between these electrodes 1 min after electrification (see Section 2.2). The surface resistivity σ is the surface resistance expressed relative to a square area. The length of the sides of this square is, in theory, immaterial [27].

Generally, current mainly flows through the surface layer of the specimen and through the moisture and surface contamination associated with it. However, the measured surface resistance also includes a nondefinable contribution from the resistance of the bulk of the sample. Thus, surface resistance cannot be measured precisely but only approximately. The measured value is generally an indication of the state of the surface at the time of measurement. The relative permittivity (see Section 2.4) of the sample under investigation affects the form and extent of contamination [27]. The current which flows as a result of contamination is, however, also influenced by the surface structure and surface properties of the specimen. Hence the surface resistivity is not a material property in the normal sense, but it can be regarded as such if the effects of contamination are taken into consideration, e.g., by appropriate preconditioning.

The test procedure has been specified by the international standard IEC 93 [27].

2.4. Relative Permittivity

Polarization leads to the internal charging of the material in a direction opposing that of the existing field. This causes a reduction of the field strength within the capacitor and a corresponding increase in the capacity when the volume between the electrodes is completely and exclusively filled with an insulating material as opposed to being empty. The ratio between the capacity of a capacitor filled with a dielectric and that of a capacitor of identical dimensions but incorporating a vacuum between the electrodes is known as the relative permittivity ε_r of the dielectric. Under d.c. conditions, the relative permittivity is characteristic for most materials, but is temperature dependent. Under a.c. conditions, it moreover depends on frequency and in certain cases on field strength.

The relative permittivity is a dimensionless comparative value. The procedure for determining capacitance is given in the international standard IEC Publication 250 [30].

Insulating materials can be divided into three groups according to relative permittivity:

1) With most materials, the positive and negative charge centers coincide. Under the influence of an electric field, electron polarization, and in some cases ion polarization, occur. Such insulating materials possess low relative permittivities of 2 – 10.
2) In the second group, a dipole moment is already present because of the molecular or crystal structure. In addition to the electron or ion polarization, the external field introduces orientation polarization, assuming of course that the dipoles are sufficiently mobile. However, this is rarely the case with organic insulating materials, or even with liquid insulation oils of relatively high viscosity. With inorganic insulating materials, the dipoles in the crystal structure may reorientate, which leads to a considerable increase in capacity. Such insulating materials are characterized by a significantly higher relative permittivity (e.g., titanium dioxide with a relative permittivity of ca. 100).
3) In ferroelectric materials that undergo spontaneous polarization (e.g., barium titanate), complete regions are reorientated by an external electrical field. This leads to relative permittivity values of ≥ 1000.

The transportation of charge carriers in an electric field and the continuous reversal of polarization in the a.c. field both incur energy losses. They cause a certain degree of heating of the capacitor dielectric. The power requirement for this is taken from the a.c. electrical field.

2.5. Dielectric Dissipation Factor

The dielectric dissipation factor (dielectric loss) is the tangent of the loss angle δ by which the phase displacement between current and voltage in a capacitor deviates from $\pi/2$ when the dielectric of the capacitor consists solely of the insulating material under investigation (Fig. 5). At the same time, it is also the ratio of the loss or effective power N_e to the reactive power N_r of a capacitor completely filled with the insulating material and subjected to an a.c. voltage.

Figure 5. Sinusoidal alternating current: voltage (U), current strength (I) and power (P) as a function of time (t)
δ = loss angle; φ = phase angle; ω = frequency

The following equation describes the relationship between the dielectric dissipation factor ($\tan\delta$) and the power factor ($\cos\varphi$) of a capacitor, where $\varphi = 90° - \delta$ and the apparent power,

$$N_a = \sqrt{N_e^2 + N_r^2}$$

$$\cos\varphi = \frac{N_e}{N_a} = \frac{N_e}{\sqrt{N_e^2 + N_r^2}} = \frac{\tan\delta}{\sqrt{1 + \tan^2\delta}}$$

The dielectric dissipation factor alone only permits comparison between the specific dissipation of different materials when the relative permittivity is the same (see Section 2.6).

The procedures for measuring the dielectric dissipation factor are described in the international standard IEC Publication 250 [30].

The highest-quality dielectric materials possess dissipation factors ($\tan\delta$) of < 0.0002 within a temperature range of 20 to 100 °C and a frequency range of 50 Hz to 1 MHz. With some insulating materials the dielectric dissipation factor is greater at low frequencies than at high frequencies. The dissipation factor generally increases with increasing temperature. In high-power systems, the heat generated by the energy losses has detrimental effects.

With glasses and ceramic materials incorporating a glassy phase, the network-modifying alkali ions have a higher mobility than the doubly bonded alkaline-earth ions. In low-loss insulating materials, the fluxing agents (which are normally based on alkali compounds) are substituted by equivalent materials based on alkaline earths. Examples include "low-loss steatite" and "alkaline-earth porcelain". Improvements in dielectric properties are, however, associated with manufacturing problems; alkali compounds used as fluxing agents cannot usually be substituted.

2.6. Loss Index

The loss index $\varepsilon'_r{}'$ of an insulating material is defined as the product of the relative permittivity and the dissipation factor

$$\varepsilon''_r = \varepsilon_r \cdot \tan\delta$$

When comparing different materials, the dielectric loss is to be preferred to the dissipation factor because the dielectric losses of identical volumes under identical field strengths and at identical frequencies behave in the same way as the respective loss indices (see Section 3.2). The dielectric loss performance P_v, relative to a unit volume of, for example, 1 cm^3 can be calculated using the following equation:

$$P_v\ (\mathrm{per\,cm^{-3}}) = \omega \cdot \varepsilon_0 \cdot \varepsilon''_r \cdot E^2 \cdot 10^{-14}\ \left(\mathrm{W/cm^3}\right)$$

where ω = angular frequency = $2\pi f$ (frequency in Hz), ε_0 = electric constant (0.08854 pF/cm), $\varepsilon'_r{}' = \tan\delta \cdot \varepsilon_r$, E = field strength (V/cm).

2.7. Breakdown Voltage

The breakdown voltage is the voltage level at which the potential between the electrodes cannot be maintained and the specimen is destroyed. It is not a material-specific property and depends on numerous parameters:

sample thickness,
rate of voltage increase
type of test voltage (d.c. or a.c.),
duration of voltage exposure,
environmental temperature,
humidity,

mechanical state of the specimen,
homogeneity,
surrounding medium, and
electrode size and positioning.

Hence all of the specifications listed in the standards (e.g., international standard IEC Publication 243) must be met exactly if comparable results are to be obtained. Even if all secondary effects can be discounted from the results (e.g., parasite discharges at the edges of the electrodes), the short-term breakdown voltage does not in general possess the character of a material-specific property. It is more a criterion for the degree of defectiveness of the insulator because the weakest regions (e.g., inhomogeneities, voids, gas inclusions) are monitored during measurement.

Breakdown behavior of insulating materials varies according to material type and testing conditions; differences depend on various breakdown mechanisms (Fig. 6). In general, a purely *electrical breakdown* is observed during impulse tests (e.g., exposure to peak loadings), and the values of breakdown voltage are correspondingly high. During long-term field strength testing, *thermal breakdown* occurs as a result of local instability caused by the heat generated by increased conductivity losses and dielectric losses (see Section 2.6). Hence the values of breakdown voltage obtained are lower, possibly also because of the low thermal conductivity. The *discharge breakdown* is of particular importance, especially during the testing of compacted materials and liquids. It is caused by discharge and destructive processes located around inhomogeneities or gas inclusions.

Figure 6. Electrical strength as a function of loading time

The electrical strength is defined as the ratio of the breakdown voltage to the distance between the two electrodes across which the voltage is applied. The term electrical strength is only valid when a uniform field exists between the electrodes.

Determination of the breakdown voltage is specified in the international standards IEC Publication 243 [31] for solids and IEC Publication 156 [32] for liquid insulating materials.

2.8. Further Electrical Tests

For special applications or investigations, supplementary test procedures have proved valuable; they have gained international recognition and have been standardized.

High-Voltage Tracking Test. This test procedure (Fig. 7) is utilized for materials that are used under severe ambient conditions in electrical engineering (e.g., high humidity, high voltages). The test enables assessment of the stability towards track formation and erosion. *Track formation* is defined as a process in which tracking and erosion are the result of an electrical discharge at or adjacent to the contaminated surface of an insulating material.

Figure 7. Schematic representation of measurement of high-voltage tracking
a) Current limiting resistor; b) Excess current switch activated by relay (c) when $I \geq 60$ mA for 2 s; c) Relay; d) Specimen (inclined plane); e) Contamination fluid; f) Voltage supply

The test must be carried out with plane specimens that are inclined at 45° and moistened with

a contamination liquid. The contamination liquid consists of distilled water containing ammonium chloride and a specified wetting agent. The specimen has the dimensions of 5×12 cm. High voltages of 2.5, 3.5, or 4.5 kV are applied to the two electrodes fastened on the smaller edges of the specimen. The contamination is allowed to flow at a specified rate over the lower surface of the specimen. The time (up to 6 h) is observed for failure caused by tracking or burning.

The tested materials are classified into four categories according to their resistance to tracking which depends on the test voltage and time. A correlation exists between this test and the low-voltage tracking test (see Section 2.1). The procedure is specified in the international standard IEC Publication 587 [33].

Arc Resistance. The test procedure according to ASTM-D 495 uses a high-voltage supply of 12.5 kV in order to generate arcing across the surface of the specimen [34]. Contrary to the high-voltage tracking procedure according to IEC Publication 587 (see above), the samples are tested in the absence of arbitrary contaminants. The electrodes are round tungsten rods. The angled tips of these rods are placed in contact with the upper or under surface of the specimen under investigation at a defined angle and at a distance of 6.35 mm apart (Fig. 8). The insulating material is classified according to the duration of the arc in seconds. At the end of each test minute, the power effect on the surface of the specimen is doubled.

Figure 8. Arc resistance test (ASTM)
Arcing occurs between the tungsten electrodes across the sample surface.

Low Voltage – High Current Arc Test. This test is used to investigate the behavior of heat-resistant materials. These are generally inorganic substances or organic materials which are highly filled with inorganic substances. The test determines (1) the distance over which a carbon arc can be extended across the surface, (2) whether the arc path is conducting, and (3) whether the material underneath the surface changes significantly after cooling. The test procedure is specified in DIN VDE 0303 part 5 [35].

Assessment of Electrostatic Behavior. Electrostatic behavior can be assessed in a test method in which either disk-shaped samples (rigid materials) or endless strips or tapes (flexible materials), are charged using contacting substrates. The field strength generated by separation of the specimen and the substrate is measured as well as the change of the charge as a function of time. Since the tests are designed to allow the selection of nonchargeable or only slightly chargeable materials, they are only of advantage for materials with a resistance at the lower end of the insulation range ($10^9 - 10^{11}\ \Omega$). The test is related to the determination of surface resistance (see Section 2.3). Procedures are specified in DIN VDE 0303 parts 8 and 14 [36], [37].

Determination of Corrosion-Promoting Effects. The corrosion-promoting effects of insulating materials can be determined by three standardized procedures specified in IEC Publication 426 [38]. A visual procedure, a tensile strength method, and an insulation resistance method are available to select between materials which have corrosion-promoting effects on nonprecious metals. With the first two tests, effects are evaluated according to the damage following contact with copper or brass. For special applications, other metals can be employed. During the evaluation of the resistance change, a decrease in resistance between taper pin electrodes or bar electrodes (measurement procedure in IEC Publication 167 [39]) after storage under humid conditions is regarded as being a criterion for the presence of a corrosion-promoting effect.

Within the fields of telecommunications, process control, and data processing, insulating materials are often employed to insulate conductors placed under a d.c. voltage. Under unfavorable

conditions, the metallic components may corrode. This can be simulated by testing under the simultaneous affects of a d.c. supply, heat (e.g., 40 °C), and environmental humidity (e.g., 92 % R.H.). The test reveals which combinations of insulating material and metal are particularly susceptible to corrosion. Judgement is made by observing color changes, destruction of test metal strips, or decreases in insulation resistance. Testing procedures are specified in IEC Publication 426 [38].

Relative Resistance to Breakdown by Surface Discharges. This method is used to estimate the working life of materials by exposing them to voltages above the discharge voltage. As with the determination of the breakdown voltage (Section 2.7), the working life decreases rapidly with increasing field strength. The partial discharges at the surface damage the material in a way similar to discharges at defects within the material.

The resistance breakdown by discharges is tested. Electric strengths refer to one year and are only comparable if sample thicknesses are identical and all test parameters are kept constant. A minimum of nine samples are tested at a minimum of three voltage settings. Large deviations must be expected because defects are irregularly distributed and the test area is relatively small. Hence the median of each set of results is used for evaluation; extrapolation to one year is performed either graphically or using regression calculations.

The test procedure is described in IEC Publication 343 [40].

Detection of Transition Regions. The detection of regions of relaxation transition using thermally stimulated discharge currents is an extremely effective method for studying inelastic effects in polymers. The high resolution allows the complex behavior of the materials to be broken down into elementary processes (Fig. 9) [22].

The interpretation of the informative discharge curves requires further intensive investigations with physical or other methods. Thermal stimulation of discharge currents can be used to solve a variety of problems [22]; examples include effects of additives on electrical and mechanical properties; compatibility in copolymers; deformation; aging; irradiation; cryogenic processing; crystallinity; conducting mechanisms; activation energy; stereo complexes; thermal histories; cross-linking; moisture content; and relationships between mechanical relaxation, elongation, and calorimetry.

2.9. Mechanical and Thermal Properties

Strength. The applicability of an insulator is primarily determined by its electrical properties. In many applications, however, mechanical properties are of equal importance.

The assessment of the mechanical strength of insulating materials is carried out using special specimens. However, the strength characteristics determined in this way cannot simply be applied to an insulation component because the strength decreases with increasing sample volume. This particularly applies to brittle, nonmetallic, inorganic materials. During the design of components and equipment, this must be taken into account and safety corrections must be made. These are known as a result of experience but they can also be approximately calculated by using techniques such as fracture mechanics and Weibull statistics.

Due to experimental difficulties however, acceptably reproducible results are only obtained in bending strength tests. Therefore standards have only been drawn up for this test. However, tensile tests are also routinely carried out when testing insulators.

The strength of ceramic insulators can be increased considerably by application of suitable glazes. The thermal expansion coefficient of the glaze must be slightly lower than that of the ceramic substrate. Following cooling after firing, the glaze is subjected to compressive stresses. When an external tensile force is applied to a glazed article, these compressive stresses in the surface must be counteracted before the tensile stresses can become effective. In glasses, similar effects are achieved by thermal hardening, i.e., by quenching from temperatures above the glass transition temperature. Chemical hardening (via ion exchange at elevated temperature) is used less widely.

With organic polymers, similar increases in strength can be gained by employing composite materials: glass or carbon fibers are incorporated into the polymer.

Material Space Filling. Apart from completely solid materials, porous substances are also used in electrical engineering. Porosity lowers the breakdown strength, therefore porous materials are not considered for high-voltage applications. In contrast to this, an open porous structure is favorable for the thermal shock resistance because porous materials have a lower Young's modulus. Porous materials are therefore often employed in thermal electrical engineering. An increase in the surface conductivity caused by the larger surface does not pose a threat because the water film is evaporated by the current flow.

Under high-vacuum conditions, porous materials are also utilized as electrical insulators to prevent the formation of continuous vapor layers.

Thermal Expansion. The thermal expansion of inorganic insulators is generally relatively low which is favorable for thermal shock resistance. A low thermal expansion also ensures good shape retention following temperature change. Inorganic insulators can withstand rapid temperature increases better than rapid cooling.

Organic substances are prone to material changes as a result of prolonged exposure to high temperature, which affects both the mechanical and electrical properties. Special organic compounds have recently been developed which are also suitable for application at elevated temperatures.

Thermal Conductivity. The thermal conductivity of the insulating materials is generally low. Hence, they can be simultaneously employed as electrical and thermal insulators. However, oxidic and nonoxidic materials are available which have a similar thermal conductivity to metallic substrates. Such insulators are normally employed when heat transfer or removal is necessary.

Specific Heat. The specific heat of the insulating material may be of significance in heat storage applications. Magnesium oxide with a specific heat of greater than $1000\,\mathrm{J\,kg^{-1}\,K^{-1}}$ is particularly suitable.

Combustion Behavior. The possibility of combustion can be a considerable obstacle regarding the use of organic insulators. Materials that do not burn at all when placed in contact with an electrical source of heat are given priority. Classification criteria include the extinguishing of the flame following removal of the heat source, or the speed at which the flames spread.

3. Insulating Materials

3.1. Inorganic Insulating Materials

Inorganic electrical insulating materials include several natural minerals (generally mica or asbestos) but also industrially manufactured products. The wide range of industrially manufactured materials includes pure glass, materials containing glassy and crystalline structural components, purely crystalline materials, and even single crystals. This broad spectrum of materials ensures a wide variety of properties. Depending upon the intended application, one or more of the following properties may be particularly pronounced: low or high relative permittivity; extremely low dielectric loss; high electrical strength at low and high frequencies; excellent insulation characteristics even at temperatures well above 1000 °C; low or high thermal conductivity; high mechanical strength.

The ferrites are also inorganic insulating materials. Ferrites are sintered products consisting

of iron(III) oxide and oxides of mono- or divalent metals. Their application within electrical engineering is primarily governed by their magnetic properties. Ferrites are generally regarded as magnetic substances (→ Magnetic Materials), although their insulation characteristics are of interest for certain applications.

3.1.1. Insulating Materials Based on Natural Minerals

3.1.1.1. Mica and Related Products
(→ Mica)

Micas are sheet silicates. Their properties are determined by mixtures of homo- or heteropolar bonds within the lamellar planes, which in turn are held together by van der Waals' forces. This type of bonding is responsible for several of mica's properties, e.g., the excellent cleaving properties parallel to the plane of the lamellae. Muscovite [*1318-94-1*], $KAl_2[AlSi_3O_{10}(OH)_2]$, and phlogopite [*12251-58-0*], $KMg_3[AlSi_3O_{10}(OH)_2]$, havefound widespread application in the electronics industry. Materials selected for insulation purposes must not contain contaminants which may adversely effect insulation properties. The mica products employed in electronics mainly originate from India.

Production and Processing. The mica is selected by hand from the mined rock and sorted according to size. Small fragments are ground and processed into powder. Larger specimens are cleaned and cleaved into sheets of thickness as low as 0.01 mm. Commercially available products are classified according to purity and surface area.

Cleaned, cleaved mica is generally processed by punching. The requirements of the punched component regarding tolerances and precise finishing are extremely high. During manufacture of capacitors, the metallizing preparation (e.g., a silver suspension) is applied directly onto the mica substrate and fired onto the surface at 600 °C following drying.

Mica products can be processed to vacuum-sealed components. Lead borate glasses are particularly suitable solders because of their low melting temperatures. Such composites can be used up to 300 °C.

Composite Insulating Materials. Large amounts of mica powder and scrap are processed to nonwoven substrates or sheets. In one process, scrap mica is heated to 800 °C; a portion of the water of crystallization escapes and causes partial cleavage of the lamellae. The mica is then immersed in sodium carbonate solution whilst still hot. Carbon dioxide gas is evolved during subsequent treatment with dilute acid, and causes complete separation of the mica lamellae. The very fine mica platelets can be processed into thin, endless, nonwoven substrates in a procedure analogous to that used in the manufacture of paper.

In another process, the mica is cleaved using a high-pressure water jet and again processed to a nonwoven fabric. The product is slightly less densely packed than that resulting from the procedure mentioned previously.

Such nonwoven fabrics, and small rejected, cleaved mica fragments are combined with natural or synthetic binders to give sheets, films, and tapes (micanite, VDE 0332, IEC 371). Suitable binders include asphalt, shellac, alkyd resins, or more recently, silicone and epoxy resins.

Micanite is a binder-containing sheet product that is manufactured using heated hydraulic presses. Commutator micanite should not contain more than 4 % binder. Sheets are ground to meet the required thickness within the tolerance limits, and then punched into commutator segments.

Heating micanite is designed for use as insulation in electric heaters; here, the binder immediately ignites when the device is first utilized. The remaining mica layer is responsible for insulation. With an appropriate binder, only short-term inconvenience is caused by the combustion products. The binder should not produce an electrically conducting residue after combustion. Shellac is a very satisfactory binder in amounts up to 3 %. Heating micanite is also manufactured from fine mica and contains 10 to 15 % silicone resin as an additive. The organic components ignite to form gaseous combustion products; the residual silica functions as a cement and confers the required strength to the insulator.

Rigid micanite, which cannot be shaped, is obtained on addition of increased amounts of binder. If subsequent shaping is desired, thermoplastic binder materials must be employed.

Mica foil consists of a thin substrate covered with one or two layers of cleaved mica or fine nonwoven mica material that are bonded together with a binder. Depending upon the type of substrate employed, the products are known as paper micanite, fabric micanite, nonwoven micanite, or film micanite (VDE 0332, IEC 371). *"Glimmerband"* (mica tape) denotes mica foil which has been slit into tapes.

Glass – mica composite materials can also be manufactured with low-melting lead borate glasses. With appropriate selection of the glass component, the semifinished article can be machined.

Properties. The properties of mica products are strongly influenced by the nature of the binder. Fine mica articles are more flexible than their cleaved mica counterparts. The application range is essentially governed by the type of binder used, but generally lies below 120 °C. With silicone resin binders, prolonged exposure to temperatures as high as 180 °C is possible. Heating micanite bound with silicone resins is able to withstand temperatures of 500 °C.

Uses. Mica wafers in their naturally occurring form are generally employed to fix electrode systems in valves and guarantee a high degree of stability, independent of the operating temperature. Further areas of application include discharge windows for high frequency energy, e.g., in transmitters operating in the microwave range, or as admission windows in counter tubes. Their reasonably high relative permittivity means that they can be used as insulators in capacitors in constant-frequency devices. The good thermal stability is utilized for insulating heating systems.

Micanites and mica foils are suitable for a variety of insulation applications, particularly in the construction of electrical equipment and plants.

3.1.1.2. Asbestos and Related Products
(→ Asbestos)

Asbestos [*1332-21-4*] is a fibrous form of magnesiumsilicate. It has an extremely high thermal stability as well as good electricaland thermal insulation capabilities even at elevated temperatures.

Asbestos materials cause severe lung damage (asbestosis), which has led to a ban on their use. They have been replaced by fiber materials produced from ceramics, particularly alumina ceramic fibers. Their properties are equal to or even better than those of asbestos. It has not yet, however, been clarified whether these alternative fibers can also cause cancer. No regulations have been laid down so far. The IEC standards and draft standards for the standardization of asbestos products have not yet been withdrawn.

3.1.2. Synthetic Inorganic Insulating Materials

Synthetic inorganic materials which are commonly used as electrical insulators are described in IEC Publication 672 [41], which has also been recently adopted as the German Standard DIN VDE 0335. Part 1 specifies terms and classification, Part 2 describes basic testing procedures, and Part 3 contains characteristic data for the individual material types.

Classification. The IEC 672 standard concerns insulating materials made from ceramics, glass, and glass ceramics, although the latter have not yet been standardized as a material type. The ceramic insulators are classified into eight groups:

C-100	materials based on alkali – aluminum silicate (porcelains)
C-200	materials based on magnesium silicate (steatites and forsterites)
C-300	materials based on titanium dioxide, titanates, stannates, or niobates (ceramics of high relative permittivity)
C-400	materials based on alkaline earth – aluminum silicates
C-500	porous materials based on aluminum silicate and magnesium silicate
C-600	materials based on aluminum silicate (mullite ceramics)
C-700	materials of high alumina content
C-800	special oxide ceramics

The glass insulators are classified into six groups (see next page).

G-100	alkali – lime – silica glasses
G-200	chemically resistant borosilicate glasses
G-300	electrically resistant borosilicate glasses
G-400	alumina – lime – silica glasses
G-500	lead oxide – alkali – silica glasses
G-600	barium oxide – alkali – silica glasses

According to IEC 672, *ceramic materials* are those substances which are shaped before firing; their main components are usually polycrystalline silicates, aluminosilicates, titanates, or oxides. *Glasses* are dense inorganic materials manufactured from a melt or by sintering, which solidify without crystallization. *Glass ceramics* are manufactured from glass, they contain a considerable crystalline content as a result of a special treatment. *Glazes* are coatings with a smooth surface which are generated in a melt process and which essentially consist of glass. They can contain coloring components or opacifiers.

The above classification of ceramic insulators is not systematic. Apparent inconsistencies are due to historical reasons. Because the preceding standard, DIN 40 685, had proven valuable for several decades and was internationally accepted, its classification system was adopted in the new IEC 672 standard. Some groups are partially defined on the basis of material aspects. However, structure is also decisive, in particular the presence of an open pore system. For example group C-500 contains only porous materials, whereas dense substances of the same chemical composition are classified in another group. Porous materials are not limited to group C-500 however. Certain groups (e.g., C-100 and C-200) contain both porous and dense varieties of a given composition.

Testing. IEC 672, Part 2 describes the testing procedures used for determining the mechanical, thermal, and electrical properties of the individual materials. Precise specification of test procedures, including sample preparation, is necessary because data are strongly influenced by the manufacturing process, shape, and dimensions of the sample, and also by the measuring procedure itself. Accordingly, data are strictly valid only for the stipulated sample and cannot be applied to samples that are of another shape or are manufactured by another process. However, modern fracture mechanics and Weibull statistics allow the properties of actual construction components to be estimated from the characteristic data obtained with standardized samples.

With glass, the thermal history of the material is important. Prestressed glass is influenced by the conditions experienced during thermal hardening. Here, it is even more difficult to deduce the properties of an insulation component from those of a standard specimen.

3.1.2.1. Porcelain

Porcelain was introduced as an electrical insulating material by W. von Siemens in the middle of the nineteenth century. Various types of porcelain have since become the material of choice for high-voltage insulators in overhead lines and transformer stations. Normal porcelain is less suitable for high-frequency and electrical heating applications because the desired properties cannot be obtained due to the presence of alkali from the fluxing agent. For special applications, alkaline-earth porcelains are available in which the alkali elements are eliminated. Only small components can be manufactured from these materials, however, because their firing interval (i.e., the temperature range between vitrification and distortion) is very small.

Material Types. The C-100 group according to IEC 672 Part 3, comprises five material types which differ with regard to their phase composition and required properties, particularly the mechanical data:

C-110	quartz porcelain
C-111	compressed porcelain (with a permitted residual porosity)
C-112	cristobalite porcelain
C-120	alumina porcelain, strong
C-130	alumina porcelain, ultrastrong

The compressed porcelains of type C-111 are only suitable for special low-voltage applications due to their permitted open porosity. Cristobalite porcelains exhibit better mechanical properties than the quartz porcelains. Alumina porcelains are now the preferred porcelains for high-voltage insulators. Their classification in the two types C-120 and C-130 takes into consideration recent developments with high-strength materials being classified as type C-130. Their manufacture is, however, difficult which explains why C-130 type materials are

only employed when extreme mechanical demands have to be met by the insulator. For normal requirements type C-120 materials, which present fewer manufacturing problems, suffice.

The use of the various porcelain types is based on differing philosophies regarding selection criteria. In western industrial nations, quartz porcelain is only used when the insulator is not exposed to mechanical loading. In general, alumina porcelains are applied even when they more than satisfy the requirements of the problem in hand. However, the universal utilization of alumina porcelains eliminates a range of problems that could arise if insulators were made in a single factory from different materials. Moreover, this improves the safety of overhead lines and transformer stations in which failure of an insulator could have a serious effect on energy supply. In contrast, in other countries (e.g., the Comecon countries), the minimization of the import of expensive synthetic alumina is the predominant factor. Here, quartz porcelain is used whenever acceptable.

Properties. Important properties of the porcelain types C-110, C-120, and C-130 are summarized in Table 1.

Raw Materials and Body Composition. The traditional hard porcelain is made from china clay, quartz, and feldspar. The plasticity of the china clays is more important than its ability to produce whiteness after firing. China clay can thus be partially substituted by plastic clay in order to improve the workability of the porcelain body.

Quartz porcelains have a high quartz content of up to 40 % which accounts for their high strength. During firing, certain types of quartz are readily converted to cristobalite, which gives rise to the formation of cristobalite porcelain types [42]. The substitution of quartz by alumina produces the alumina porcelains; type C-120 contains up to 30 wt% and type C-130 up to 40 wt% alumina.

Manufacture (→ Ceramics, General Survey). Molding and shaping are carried out using conventional processes employed in the ceramic industry. Low-voltage insulation components are manufactured by pressing techniques. High-voltage insulators are produced by extrusion of a pug with a vacuum extruder and subsequent cutting either after partial drying in a "leather-hard" state (Fig. 10), or after complete drying. The pug itself can be manufactured by isostatic pressing to give a dry pug, suitable for immediate machining. Care must be taken to ensure that any dust generated during machining is removed completely.

Figure 10. Machining of an insulator with photoelectric control

The shaped components are coated with a raw glaze, dried, and fired in a tunnel, chamber, or oven kiln.

Semiconducting glazes coated onto insulators may influence the shape of the electric field and contribute to the prevention of short circuiting due to condensation. However, they can cause problems during operation, and have therefore not yet made a general breakthrough, although they would permit the more compact construction of transmission lines.

Uses. Low-voltage insulation components made from compressed porcelain are employed in a variety of applications including coupler terminal strips, cartridge fuses, terminal blocks, and inserts for plugs and sockets. They may be used in combination with organic polymers.

A wide range of porcelain insulators are employed in high-voltage applications: support in-

Table 1. Important physical properties of porcelain types C-110, C-120, and C-130 classified according to IEC 672

Property	C-110	C-120	C-130
Open porosity, vol%	0	0	0
Bulk density, g/cm^3	>2.2	>2.3	>2.5
Bending strength, N/mm^2			
Unglazed	>50	>90	>140

Dielectric dissipation factor (tan δ) at 20 °C and 50 Hz	<0.025	<0.025	<0.030
Volume resistivity, $\Omega \cdot$ cm			
at 20 °C	$>10^{13}$	$>10^{13}$	$>10^{13}$
at 600 °C	$>10^{4}$	$>10^{4}$	$>10^{4}$

sulators, suspension insulators, and terminal insulators for overhead line construction; insulator housings able to withstand extreme mechanical loading; or as external shielding for voltage transformers of heights up to 5 m and diameters of 1 m. Lead-through insulators can also be produced with multiple bore holes running parallel to the longitudinal axis.

The alkaline earth porcelains are mainly employed as resistor bodies.

3.1.2.2. Steatite

The term steatite [*14807-96-6*] has two meanings, firstof all as a synonym for the fine-grained variety of talc, and secondly fora special ceramic material manufactured from this talc.

To avoid confusion, the term steatite is used here to denote the ceramic product. The term talc (and not steatite) is used for the ceramic raw material regardless of its crystal size. Normally, however, the term talc solely denotes the coarse-grained variety of the mineral.

Material Types. Group C-200 according to IEC 672 contains six types of material based on talc:

Type C-210	steatite for low-voltage applications (not dense)
Type C-220	steatite
Type C-221	low-loss steatite
Type C-230	steatite, porous
Type C-240	forsterite, porous
Type C-250	forsterite, dense

The most important materials in group C-200 are steatite (type C-220) and low-loss steatite (type C-221). Type C-250 is formed from a MgO-enriched body and contains forsterite [*15118-03-3*] (Mg_2SiO_4) as the main crystalline phase. The porous types (C-230 and C-240)allow the manufacture of high precision components from fired semifinished products using conventional machining techniques.

Properties. Several of the most important properties of the C-220 and C-221 types are listed in Table 2.

Type C-220 steatite is manufactured using feldspar as a fluxing agent. This yields an adequate firing range for the production of larger items. With low-loss steatite (type C-221), dielectric properties are considerably improved when barium carbonate is used as a fluxing agent. This material is thus also suitable as a dielectric for capacitors. For some applications its relatively high mechanical strength is also of significance. With the exception of high-voltage insulators, low-loss steatite is the most popular variety of steatite.

Compared with the porcelains, the steatites have outstanding electrical properties. Only the best alumina porcelains have mechanical properties comparable with those of steatite. Recent investigations have shown that the resistance of steatite to crack propagation is slightly greater than that of alumina porcelain [43].

Raw Materials. The preferred raw material for the manufacture of steatite is talc [*14807-96-6*], $Mg_3[Si_4O_{10}(OH)_2]$ in its fine crystalline form (→ Talc). The random orientation of the crystals in this talc allows the manufacture of ceramic products with low particle

Table 2. Important physical properties of steatite types C-220 and C-221, as well as forsterite type C-250 classified according to IEC 670

Property	C-220	C-221	C-250
Open porosity, vol%	0	0	0

Relative permittivity at 20 °C and 50 Hz	6	6	7

orientation. One of the most important talc deposits is found near Göpfersgrün – Thiersheim in the Federal Republic of Germany. It represents the main basis for the worldwide manufacture of large, high-voltage steatite insulators. Talc for use in ceramics originates in Australia, the United States, Spain, and China.

Only talcs with low levels of contamination can be used as a raw material for the manufacture of steatite. The maximum upper limits which can be tolerated are 1.5 wt% Al_2O_3 and 2.0 wt% Fe_2O_3 [44]. Recently, calcia has been regarded as less critical and may be present in amounts up to 1 wt% [45]. The steatite body contains 80 to 90 % talc along with 5 to 10 wt% of a fluxing agent (in steatite, feldspar; in low-loss steatite, barium carbonate) and plastic clay to improve the processing properties.

Manufacture. Components from steatite are produced according to the general principles employed in the ceramics industry (→ Ceramics, General Survey). All molding and shaping techniques can be employed such as casting, shaping in the plastic state, or pressing, and when necessary subsequent machining in the leather-hard or dried state. The most important technique, particularly for small components, is pressing. The dry pressing process only gained widespread use after its development with talc bodies. Talc bodies have proved to be particularly suitable for this technique because the low hardness of talc (Mohs hardness = 1) guarantees a long service life.

The steatite components are usually fired at 1300 – 1400 °C in an oxidizing or reducing atmosphere. The firing interval is lower than that of porcelain, particularly with low-loss steatite. The lower firing interval for steatites is mainly responsible for the fact that steatite insulators can only be manufactured with maximum heights of ca. 1.2 m.

During firing, dry-pressed components shrink by only 10 to 12 %, and hence are suitable as insulator components with high dimensional tolerances.

Metal layers of silver, platinum, iron, or molybdenum can be used as electrodes on steatite or as a soldering base for joining steatite to metals of other ceramic components.

During firing, the talc is transformed to protoenstatite, $MgSiO_3$. The additives (clay and feldspar or barium carbonate) form a melt phase which vitrifies on cooling; the glass content of the fired body may be as high as 25 to 50 vol% [46]. An excess of silica leads to crystallization of cristobalite from the melt; this occurs in certain steatite bodies, but particularly in feldspar steatites. Improved thermal shock resistance is observed with steatites in which the silica has been completely taken up by the melt phase, for example in most low-loss steatite products containing silica-free fluxing agents.

Uses. Steatite finds widespread use as an insulating material in electrical engineering. In low-voltage applications, it is employed for the manufacture of insulation components in which a high degree of dimensional precision is required (e.g., for mechanically mounted components). Typical insulators made from steatite include sockets, inserts for plugs, levers and rollers

for rotary and rocker switches, holders, and cartridge fuses. Steatite has many advantages over porcelain when greater mechanical loading has to be withstood.

In high-voltage applications, steatite can now be replaced by alumina porcelain. Abrasion of machining tools is, however, considerably lower with steatite bodies. On the other hand, alumina porcelain bodies are easier to fire and are suitable for the manufacture of components much larger than those made of steatite. Steatite shows clear advantages in high-frequency applications, for example as bases for antenna masts and for terminal insulators in transmission masts.

Low-loss steatites are suitable for the manufacture of capacitors, e.g., the complex thick-walled capacitors used in high-voltage applications.

Talc Bodies Enriched in Magnesia. The crystalline phase *forsterite,* Mg_2SiO_4, is deliberately formed in fired bodies of the material types C-240 and C-250 by enriching the talc with magnesia (e.g., by addition of magnesite, $MgCO_3$). Several properties of type C-250 materials are summarized in Table 2.

The outstanding properties of forsterite ceramics include the particularly low dielectric losses and the large thermal expansion coefficient. The latter permits low-stress soldering to iron or nickel substrates which possess coefficients of thermal expansion of similar magnitude. This advantage of forsterite is, however, obtained at the expense of low thermal shock resistance.

Zircon-Containing Steatite. Zircon [*1490-68-2*] , $ZrSiO_4$, can be sinteredto produce a dense material only with difficulty. When used as an additivefor steatite, and, in some cases, for porcelain, the thermal expansion of the resulting material is reduced, and hence the thermal shock resistance is improved. The amount of zircon additive can reach 60 wt%. The dielectric properties of the zircon steatites are adversely affected because losses increase significantly above 1 MHz. The relative permittivity of zircon steatite is 8, this is sometimes undesirably high for certain insulators.

3.1.2.3. Materials for Electrical Heat Engineering

Two of the most important demands for the use of ceramic materials in electrical heat engineering are adequate stability at high temperature and favorable thermal shock resistance.

The thermal shock resistance is determined by the phase composition: compositions which approach that of a eutectic melt at relatively low temperatures and are therefore unsuitable. Thermal shock resistance increases with increasing mechanical strength and thermal conductivity, but also with decreasing modulus of elasticity and decreasing thermal expansion. It also depends upon external conditions, such as shape and dimensions of the article, as well as on the rate of heat exchange with the surroundings. In this respect, the thermal shock resistance is not a material constant.

Young's modulus is related to the structure of the material; it is lower with porous structures than with dense structures.

The most important factor controlling thermal shock resistance is thermal expansion. In materials with a low thermal expansion coefficient, the product is only exposed to low stresses, even if the thermal shock is high.

Hence the most suitable materials for electrical heat engineering are those which are porous and possess a low thermal expansion coefficient.

Material Types. Group C-400 defined in IEC 672 contains two types of material:

C-410	cordierite dense
C-420	celsian dense ($BaAl_2Si_2O_8$)

Type C-410 materials are used more widely.

Group C-500 contains the following porous materials:

C-510	materials based on grog (fireclay, chamotte)
C-511	materials based on grog containing magnesium oxide
C-512	materials based on grog containing magnesium oxide
C-520	materials of high cordierite content
C-530	materials of high alumina content

Types C-511 and C-512 contain cordierite [*12182-53-5*], $Mg_2Al_4Si_5O_{18}$, and mullite [*55964-99-3*], $Al_6Si_2O_{13}$. They differ in the number andsize of the pores, and hence also in the strength and thermal shock resistance. The composition of type C-520 materials approaches that of cordierite. The high alumina content of the type C-530 materials enables high application temperatures up to 1300 °C.

Properties. Table 3 contains typical properties of porous and dense materials used in electrical heat engineering.

Materials Containing Cordierite. Even as early as the 1930s, addition of talc to clay-based material had been shown to reduce their thermal expansion coefficient, and hence increase their thermal shock resistance. Talc and clay react during firing to give cordierite. Optimum results are obtained with approximately 60 % clay and grog (chamotte) and 30 % talc (type C-520 material according to IEC 672). Types C-511 and C-512 contain ca. 10 % talc.

A distinct disadvantage of cordierite materials is their narrow firing range. Consequently it is normal to refrain from vitrifying the articles, and concentrate on porous products that have a lower Young's modulus and therefore exhibit improved thermal shock resistance. If dense materials of type C-410 are required for special applications, then small amounts of a fluxing agent must be added; feldspar has proved particularly effective in this respect. Such materials are not only inferior as regards their thermal shock resistance, but also in their electrical insulation characteristics. This is because of the contribution of the alkali ions to their electrical conductivity at high temperatures. Furthermore, the porous materials allow higher application temperatures (ca. 1200 °C) than their dense counterparts. However, dense cordierite materials are required for some applications.

Lithium Aluminum Silicates. Lithium aluminum silicates possess an even lower thermal expansion coefficient than cordierite.

The materials have not been standardized. Raw materials are petalite, $LiAlSi_4O_{10}$, and to a lesser extent spodumen, $LiAlSi_2O_6$, or eucryptite, $LiAlSiO_4$. Widespread application of these materials has been somewhat hindered because of the scarcity of the raw materials, and because of the extremely narrow firing range. Therefore their excellent thermal shock resistance is only used in exceptional cases.

3.1.2.4. Alumina Ceramics (→ Ceramics, Electronic)

The inorganic insulating materials discussed in Section 3.1.1 are all produced from natural materials. Aluminas and the other materials discussed in this section are based on synthetic materials produced by the chemical industry.

Material Types. In IEC 672, alumina materials are classified in group C-700. They differ in their minimum alumina contents. In all cases, the alumina content is so high that the insulating material contains α-aluminum oxide as the predominant or even exclusive crystal phase.

Properties. The important physical properties of alumina ceramics are summarized in Table 4. Properties generally improve with increasing alumina content (higher number).

Alumina ceramics combine a range of remarkable properties. With the high percentage types (C-799), a strength of $\geq 500\,N/mm^2$ can be achieved, particularly if crystal growth can be suppressed during sintering. Mechanical strength is maintained up to temperatures of 1000 °C. Thermal conductivity reaches a level equivalent to that of metallic lead, especially in the high percent types. Alumina substrates are amongst the best electrical insulating materials under all application conditions.

Production. Raw materials include calcined aluminas which are obtained from natural bauxites by the Bayer process (→ Aluminum Oxide). The precipitation and calcination conditions govern the most important properties in ceramic applications, such as crystal size and sintering capability. Since the aluminas are not plastic, molding and shaping necessitates the addition of organic plasticizers which must be removed prior to firing.

Table 3. Important properties of materials classified in groups C-400 and C-500 of IEC 672

Property	Fine fire clay	Materials containing cordierite			Materials containing alumina

For solder connections, alumina components are metallized, preferably by the moly–manganese paste process (→ Ceramics, Ceramic–Metal Systems, Chap. 4.1.). Alternatives are active soldering with titanium hydride or use of solders containing titanium under conditions of high vacuum or in an oxygen-free atmosphere.

Uses. Alumina ceramics find many applications within the field of electronics and electrical engineering due to their outstanding insulation properties even at very high frequencies. Furthermore, their large thermal conductivity means that any heat generated as a result of the dielectric losses in electrical circuits and components can easily be removed. Examples of uses include housings for high-frequency electron tubes, rectifier housings, high-frequency coupling windows, solderable bypasses, resistor substrates, substrates for potentiometers, and substrates for microelectronics.

3.1.2.5. Special Oxide Ceramics

Group C-800 of IEC 672 comprises several special oxide ceramic insulating materials: beryllia (type C-810), magnesia (type C-820), and zirconia (type C-830).

Beryllia Ceramics. Beryllia ceramics (type 810 according to IEC 672) possess similar properties to alumina ceramics; the main differences are the lower density (<3.0 g/cm^3) and the large thermal conductivity which is approximately one order of magnitude higher than that of alumina. In substrates, potentiometer mounting plates, and housings for semiconductor components, the material effectively removes heat produced by dielectric losses. However, beryllia dust is highly toxic and attacks the lungs, necessitating comprehensive safety precautions during manufacturing (beryllia in finished products is of no danger provided that no dust is generated). This, along with the limited availability of

raw material deposits, means that beryllia components are extremely expensive. Their use is restricted to a small number of applications that involve particularly high demands, e.g., in the aerospace industry.

Magnesia Ceramics. Magnesia is standardized in IEC 672 as type C-820, a porous ceramic insulating material. Its main applications are found within the field of electrical heat engineering, primarily because of its high specific heat for use in heat storage elements, but also because of its favorable thermal conductivity and excellent insulation properties for use as an insulator in tubular heating elements. In the latter case, the ceramic is inserted into the cavity between the heating wire and the outer tubes and subsequently crushed, compacted, and solidified by rolling, hammering, and pressing.

Zirconia Ceramics. Zirconia ceramics are standardized as type C-830 in IEC 672. They can only be used as insulators at room temperature because the oxygen ions of zirconia become highly mobile at higher temperatures and the material then acts as a semiconductor. This principle forms the basis of the widespread application of zirconia as a sensor for determining the partial pressure of oxygen.

3.1.2.6. Insulating Materials Containing Titanium Oxide and Titanates

Whereas the materials discussed so far are generally employed purely as insulators, the use of components containing titanium dioxide and titanates is governed by their high relative permittivity.

Material Types. Group C-300 of IEC 672 is subdivided into seven types:

C-310	titanium dioxide
C-320	magnesium titanate
C-330	titanium dioxide incorporating other oxides as additives
C-331	as for type C-330
C-340	strontium, calcium, and bismuth titanates
C-350	barium titanate
C-351	barium titanate

The materials differ with respect to their relative permittivity, the associated temperature coefficient, and the dielectric dissipation factor. Types C-310, C-320, C-330, C-331, and C-340 have been classified according to international regulations as Type I capacitor materials; according to DIN 41 920, they are subdivided on the basis of the temperature coefficients of their relative permittivities. Material types C-350 and C-351 have a high relative permittivity and are classified as Type II substances.

Titanium Dioxide and Mixed Dielectrica Based on Rutile. Titanium dioxide [*13463-67-7*] crystallizes in the rutilestructure, which is always formed at temperatures above 1000 °C evenwhen the metastable anatase is used as a starting material.

The relative permittivity of rutile is strongly anisotropic. In polycrystalline materials with random crystal orientation, the relative permittivity has an average value of 117. The temperature coefficient of the relative permittivity is highly negative ($-0.001\,K^{-1}$).

Properties (see Table 5) can be modified by additives, such as zirconium oxide, lanthanum oxide, or magnesium titanate. These additives possess considerably lower relative permittivities and positive temperature coefficients. By following a logarithmic mixing relationship for relative permittivity, or a linear mixing relationship for the temperature coefficient, specific materials with tailored properties can be obtained. The temperature coefficient and the relative permittivity decrease with increasing additive concentrations. Dissipation factors are low ($\leq 10^{-3}$); with mixed dielectrics containing zirconium oxide, they are independent of frequency up to 10^8 Hz.

Dielectrics of this type are used to compensate for the increase in capacitance with temperature produced by other components. The primary criterion for the selection of the dielectrics is the magnitude of the negative temperature coefficient of the relative permittivity rather than the permittivity itself.

Materials Containing Titanates. The properties of titanate-based insulating materials are listed in Table 6.

Type C-320 IEC 672 comprises materials based on magnesium titanate. The outstanding

feature of these materials is the excellent temperature stability of the relative permittivity, the values of the latter lie between 12 and 40.

Type I capacitors with extremely high negative temperature coefficients for the relative permittivity (up to 0.006 K^{-1}) can be obtained with materials based on strontium and/or calcium titanate (type C-340 in IEC 672).

Barium titanate [*12047-27-7*], $BaTiO_3$, is the most important alkaline-earth titanate (→ Ceramics, Electronic). It also finds application as a piezoelectric material.

Because of their piezoelectric properties, considerable interest has also been centered on titanates that contain lead in the form of mixed crystals with zirconates, stannates, and niobates.

Like all of the other titanates listed above, barium titanate crystallizes to give a deformed perovskite structure. Slight distortions lead to a tetrahedal structure at room temperature, a rhombic structure below 0 °C, and trigonal symmetry below −90°C. The most significant property of the distorted structure without a center of symmetry is its extremely large relative permittivity, particularly in the direction perpendicular to the main crystal axis (Fig. 11). Maximum relative permittivity values are observed at each of the crystallographic transition temperatures, but are accompanied by a maximum in the dielectric loss (Fig. 12). This results in a strong, nonlinear temperature dependence of the relative permittivity. The dipoles in the deformed crystal interact mutually and are aligned in parallel in small areas known as domains. The direction of dipole orientation in neighboring domains is reversed so that the whole system assumes an energy minimum and does not have a net external charge. On applying an external electrical field, the domains become oriented in the direction of the field to an extent proportional to the electrical field strength. Because of the anisotropy of the dielectric properties, this reorientation of the domains is coupled with a change in the relative permittivity, i.e., the relative permittivity is also dependent upon field strength. The combination of phenomena discussed here is known as fer-

roelectricity (see also → Ceramics, Electronic, Chap. 3.).

Above a certain temperature known as the Curie temperature (in the case of barium titanate 120 °C), the structure becomes strictly cubic, and the ferroelectric properties are lost. Above the Curie temperature T_c, the changes in the relative permittivity with temperature are described by the Curie – Weiss law:

$$\varepsilon_T = \frac{C}{T - T_c}$$

where C is the Curie constant and ε_T is the relative permittivity at temperature T. Compounds exhibiting a perovskite structure tend to form mixed crystals. Hence Ba^{2+} can be replaced by Sr^{2+}, Pb^{2+}, and to a certain extent also by Ca^{2+}; Ti^{4+} can be substituted by Zr^{4+} or Sn^{4+}. Similarly, ion combinations can be incorporated providing the ionic radii are equivalent and a balance of charge is attained (complex perovskites). These substitutions produce changes in the relative permittivity and its temperature dependency, as well as in the dielectric loss and the Curie temperature. In this way, a wide range of insulating materials with differing properties can be produced.

Figure 11. Relative permittivity of barium titanate along the a and c crystal axes as a function of temperature

Figure 12. Temperature dependence of the relative permittivity (ε_r) and the dielectric loss ($\tan\delta$) of polycrystalline barium titanate

Certain oxide additives (e.g., a small excess of titanium dioxide) act as grain boundary phases which prevent crystal growth. In small crystals, ferroelectric domains are still formed, but their changes of position and size in an external field are considerably hindered. Materials of this kind show reduced hysteresis loss, and the curve of $\varepsilon_T = f(T)$ flattens out in the vicinity of the Curie temperature. Because of their low losses, such dielectrics are employed as contact-protective capacitors. Extremely small crystals (ca. 50 nm) cannot be reorientated in an external electric field and hence do not exhibit ferroelectric properties.

Other additives (e.g., bismuth oxide, bismuth titanate, zinc oxide, or zinc titanate) extend the firing interval, but also change the shape of the curve $\varepsilon_T = f(T)$. Bismuth titanate additives produce dielectric materials of low temperature dependency in their electrical properties.

If a dielectric is made from two perovskite materials that do not form or only partially form mixed crystals, then the change in the relative permittivity between the relevant Curie temperatures is low. Examples of such dielectrics include those containing calcium and barium titanate.

In titanate-based products, the raw materials are thoroughly mixed and calcined onto a frit, which is subsequently ground, shaped, and fired. In order to prevent chemical reduction of the titanium, which would cause the article to have semiconductor properties, capacitor materials must be fired in an oxidizing atmosphere. The electrodes and contact layers are formed by depositing metal coatings, generally silver.

Types C-350 and C-351 in IEC 672 have a relative permittivity below and above 3000, respectively.

The main use of titanate-containing dielectrics is as capacitors in high-frequency applications. Examples include the bridging of d.c. resistors and the manufacture of capacitive couplers. Furthermore, perovskite-based materials containing titanate have gained considerable significance as piezoelectric components.

When titanates are fired under reducing conditions, semiconductor materials are obtained which reoxidize at the interfacial regions during the firing of metallizing layers. This process is used to produce intergranular barrier layer capacitors which possess particularly high capac-

ities due to the low thickness of the dielectric layer (Type III dielectrics).

3.1.2.7. Nonoxide Ceramics

More recently, increased interest has been shown in nonoxide inorganic materials because of several unusual properties. They have a very high mechanical strength, even at elevated temperature. The most important materials are compounds of elements of groups 3, 4, and 5 of the periodic table. Silicon nitride (Si_3N_4), silicon carbide (SiC), and aluminum nitride (AlN) deserve special mention.

The essentially homopolar bonding character between the atoms of these compounds determines their physical properties to a large extent, but also causes problems during the manufacture of components when using traditional procedures employed in the ceramic industry. Production is thus more complicated and more expensive. Nonoxide ceramic materials are only suitable as insulating materials when their extraordinary properties provide a particularly elegant solution for a given problem. Silicon nitride [*12033-89-5*] andaluminum nitride [*24304-00-5*] are used as electrical insulators.

Silicon carbide is not suitable for electrical insulation purposes because its electrical conductivity increases strongly with temperature; it is even employed as a high-temperature heating element.

The thermal conductivity of aluminum nitride is considerably greater than that of aluminum oxide. The low density of 3.2 g/cm^3 makes it a suitable alternative to beryllium oxide when the effective removal of heat generated by dielectric losses is important. At increasing temperatures, the decrease in thermal conductivity of aluminum nitride is considerably lower than that of the oxide materials. A further advantage of aluminum nitride, especially as a substrate for high-power silicon components, is the fact that the thermal expansion coefficient is closer to that of silicon than any other potential substrate materials.

Silicon nitride exhibits similar insulation properties to aluminum oxide, but its thermal expansion coefficient is only half as large, and correspondingly shows greater thermal shock resistance. This characteristic is of considerable importance in glow plugs in diesel engines.

3.1.2.8. Glass (→ Glass)

Glass materials have been used as insulators in electrical engineering for many years. The systematic classification and establishment of minimum requirements occurred during their incorporation in the IEC standard 672.

Material Types. Glass materials used as electrical insulators can be classified into six groups:

G-100	alkali – lime – silica glasses
G-200	chemically resistant borosilicate glasses
G-300	electrically resistant borosilicate glasses
G-400	alumina – lime – silica glasses
G-500	lead oxide – alkali – silica glasses
G-600	barium oxide – alkali – silica glasses

Group G-100 consists of:

Type G-110 alkali – lime – silica glasses, annealed
Type G-120 alkali – lime – silica glasses, toughened

The mechanical strength is increased tremendously by prestressing (Type G-120).

Group G-300 consist of:

Type G-310 borosilicate glasses, low loss
Type G-320 borosilicate glasses, stable to high voltage

Properties. Several of the requirements specified in the IEC 672 are summarized in Table 7. A range of properties of glass are governed by its chemical composition. Characteristic data can be determined by multiplying the content of a glass component (expressed in percent) by a property-specific factor, and summing the calculated values. Properties that can determined in this way include the thermal expansion and the surface energy.

Production. Glass is produced by melting appropriate mixtures of raw materials and molding them in the molten state (→ Glass). On cool-

ing, the melt vitrifies to form the desired component. Residual stress can be removed by annealing. However, compressive stresses can also be deliberately generated in order to increase the mechanical strength of the component.

Insulator components are mainly shaped by pressing the viscous melt in steel molds, although recently, extrusion has been introduced as an additional shaping method. Glass can also be processed by blowing.

Uses. The applications for glass in electrical insulator are determined by properties that can be particularly well optimized in certain types of glass; these properties are indicated by bold type in Table 7.

Glass materials from group G-100 are frequently employed for overhead line insulators. Cap insulators are most common and are combined to form long chains. Long rod insulators are also used but are more difficult to manufacture.

Glass insulators have been increasingly employed with overhead lines. Their major advantage is that faults can easily be identified because they are transparent; slightly defective components can therefore be exchanged before a major failure occurs.

The high requirements placed on the mechanical properties of suspension insulators for overhead lines are met by toughened glass. Glass ceramics (which have not yet been included in the IEC standard) have also been recently employed because they have a high strength combined with a low thermal expansion coefficient and correspondingly an improved thermal shock resistance (→ Glass Ceramics).

Glass materials of type G-200 (chemically resistant borosilicate glass) are used in discharge lamps. The low coefficient of thermal expansion resulting from the use of boron oxide ensures that the glass has a high thermal shock resistance. Boron also improves chemical resistance.

Type G-310 glass materials exhibit favorable properties for lead through insulators in high-frequency applications. They are also suitable for glass components designed to have capacitor functions. Type G-320 materials are employed in valves for high-voltage applications, e.g., for X-ray tubes.

Type G-400 glass materials were developed to have optimum properties for high-performance halogen lamps; their properties have now been standardized.

Type G-500 and G-600 glasses are employed when metallic components, particularly those based on nickel–iron alloys, have to be sealed into electric lamps and valves. They have a low glass transition temperature and a large thermal expansion coefficient to ensure that only weak mechanical stresses are generated in the composite system. Because of the incorporation of heavy metal oxides, they are also used in televisions to absorb the generated X-rays. Glass materials containing lead can change on exposure to X-rays and electron beams, and thus become discolored or even produce tracking currents. In applications where these effects must be excluded, lead-free glasses of type G-600 must be employed.

3.2. Organic Insulating Materials

The following discussion of the most common organic materials employed as electrical insulators includes products that meet all or many of the imposed requirements. This does not mean that all of the products are employed in large amounts in the electronics industry. The compilation is by no means complete, and is intended merely to provide an overview. Description of the products has been kept brief. Details are available from manufacturers' information and specialist publications. Examples of trade names are given for each group of polymers but these lists are by no means exhaustive. Most of the polymers are described in detail elsewhere in the encyclopedia. Emphasis has been placed on graphic representations–the relief diagrams. As opposed to tables, these diagrams allow the rapid visual assessment of the suitability of a material for a given electrotechnical project. Different materials can also be compared. The block lengths demonstrate the quality variation of a particular material class. Each diagram shows:

1) the *comparative tracking index* (CTI) measured according to IEC 112 (see Section 2.1)
2) the *volume resistivity* (ϱ) measured according to IEC 93 at 23 °C and 50 % R.H. (see Section 2.2)
3) the *surface resistivity* (σ) measured according to IEC 93 at 23 °C and 50 % R.H. (see Section 2.3)
4) the *loss index* ε''_r measured according to IEC 250 at 1 kHz, 23 °C, and 50 % R.H. (see Section 2.6)
5) and the *relative permittivity* ε_r measured according to IEC 250 at 1 kHz, 23 °C, and 50 % R.H. (see Section 2.4)

The electric strength is not shown because although the test results obtained in accordance with the standard can be used for detecting changes or deviations from normal characteristics resulting from processing variables, aging conditions, or other manufacturing or environmental situations, they can seldom be used directly to determine the behavior of insulating materials in a real application. Measured values of the electric strength are affected by many factors (Section 2.7), but these factors are not specified when the results are published.

The significance and determination of the parameters presented in the graphics are described in Chapters 1, 2, and 4. Values can easily be read from the plots. The dielectric dissipation factor is obtained by dividing the loss index (column 4) by the corresponding value for relative permittivity (column 5).

3.2.1. Thermoplasts

Thermoplasts, also referred to as plastomers, are solid synthetic resins which can be repeatedly softened without chemical modification by heating in a relatively narrow temperature range. They can be shaped while soft and generally consist of linear molecules. Physical properties of the thermoplasts are compiled in Table 8.

Acrylonitrile – Butadiene – Styrene. Physical properties are given in Table 8 and electrical properties in Figure 13 (see also → Polystyrene and Styrene Copolymers).

Figure 13. Relief diagram of electrical properties of acrylonitrile – butadiene – styrene

Special properties: high impact toughness, thermally stable, unlimited shaping characteristics, limited stability to UV radiation.

Uses : casings for office machinery, electrical industry, electronics, telecommunications, protective insulating components.

Trade Names: Cycolac (Borg Warner Chemicals, USA); Kralastic (USS Chemicals, USA); Novodur (Bayer, FRG); Terluran (BASF, FRG); Diapet (Mitsubishi Rayon Co., Japan); Ravikral (EniChem, Italy).

Acrylonitrile – Styrene – Acrylic Ester. Physical properties are given in Table 8 and electrical properties in Figure 14.

Styrene – acrylonitrile copolymer (SAN)	[*9003-54-7*]	1.1	70	4	85
Styrene – butadiene copolymer (SB)	[*9003-55-8*]	1.1	40	35	60

Figure 14. Relief diagram of electrical properties of acrylonitrile – styrene – acrylic ester

Special properties: stable to UV radiation, weather-resistant, thermally stable over long periods, unlimited shaping characteristics.

Uses: insulators, insulating material, ventilators, casings for electronic equipment, electrical industry, electronics, telecommunications, protective insulating components.

Trade Names: Richform (Richmond Div. of Dixico, USA); Luran S (BASF, FRG); Geloy (General Electric, USA).

Cellulose Acetate. Physical properties are given in Table 8 and electrical properties in Figure 15 (see also → Cellulose Esters).

Figure 15. Relief diagram of electrical properties of cellulose acetate

Figure 16. Relief diagram of electrical properties of cellulose acetate butyrate

Figure 17. Relief diagram of electrical properties of cellulose propionate

Special properties: antistatic properties despite high electrical resistance, crystal clear, tough, hard, scratch-resistant, insensitive to stress cracking, readily dyeable with brilliant colors, not permanently weather-resistant, less suitable for precision components.

Uses: tool handles, electric insulation films, lights, casings.

Trade Names: Dexel (Courtaulds Plastic Group, UK); Ampol (American Polymers, USA); Tenite (Eastman Chemical International, USA).

Cellulose Acetate Butyrate. Physical properties are given in Table 8 and electrical properties in Figure 16 (see also → Cellulose Esters).

Special properties: antistatic despite high electrical resistance, crystal clear, tough, hard, scratch resistant, insensitive to stress-cracking, readily and brilliantly dyeable, not suitable for precision components.

Uses: tool handles, electric insulation films, lights, casings.

Trade Names: Ampol (American Polymers, USA); Tenite (Eastman Chemical International, USA).

Cellulose Propionate. Physical properties are given in Table 8 and electrical properties in Figure 17 (see also → Cellulose Esters).

Special properties: antistatic despite high electrical resistance, crystal clear, tough, scratch-resistant, insensitive to stress cracking, readily dyeable with brilliant colors, not suitable for precision components.

Uses: tool handles, electric insulation films, lights, casings.

Trade Names: Ampol (American Polymers, USA); Tenite (Eastman Chemical International, USA).

Perfluoro(Ethylene – Propylene). Physical properties are given in Table 8 and electrical properties in Figure 18 (see also → Fluoropolymers, Organic, Chap. 2.3.).

Special properties: nonflammable, weather-resistant, resistant to solvents, no water uptake, physiologically inert, stable to pressure.

Uses: flexible printed circuits, coaxial cables for computers, cable insulation, shrinkable tubes.

Trade Names: Teflon (Du Pont, USA); Neoflon (Daikin Kogyo Co., Japan).

Polyamide. Physical properties are given in Table 8 and electrical properties in Figure 19 (see also → Polyamides).

Special properties: normal minimum water content of 2.5 %, prone to stress cracking when freshly injected, impact resistant, viscoelastic, puncture resistant, dynamic-loading capability, good slip properties.

Uses: high-voltage insulation, multiple connecting plugs, relays, extinguishing chambers, wear-resistant insulation and sleeve materials for cable technology.

Trade Names: Ultramid (BASF, FRG); Durethan (Bayer, FRG); Technyl (Rhône-Poulenc Specialities Chimiques, France); Grilon (Ems-Chemie, Switzerland); Zytel (Du Pont, USA); Maranyl (ICI, UK).

Polyamide 12-Resin. Physical properties are given in Table 8 and electrical properties in Figure 20.

Figure 18. Relief diagram of electrical properties of perfluoro(ethylene – propylene)

Figure 19. Relief diagram of electrical properties of polyamide

Figure 20. Relief diagram of electrical properties of polyamide 12-resin

Figure 21. Relief diagram of electrical properties of polyamideimide

Special properties: resistant to organic solvents, fuels, oils, weak acids and alkalis.

Uses: casings, components for electrical devices.

Trade Names: Vestamid (Hüls, FRG); Rilsan (Atochem, France); Grilamid (Ems-Chemie, Switzerland).

Polyamideimide. Physical properties are given in Table 8 and electrical properties in Figure 21.

Special properties: resistant to elevated and cryogenic temperatures; nonmeltable; resistant to hydrocarbons, weak acids, and weak alkalis; resistant to highly energetic radiation sources; very low coefficient of friction.

Uses: special material for relays and multiple connection plugs used under extreme conditions, printed circuits, suitable for solderable connecting cable.

Polybutene. Physical properties are given in Table 8 and electrical properties in Figure 22 (see also → Polyolefins).

Figure 22. Relief diagram of electrical properties of polybutene

Figure 23. Relief diagram of electrical properties of poly(butylene terephthalate)

Figure 24. Relief diagram of electrical properties of polycarbonate

Special properties: high long-term stability, low tracking propensity at high temperature, high stress cracking stability, resistant to low temperature, easily weldable.

Uses: insulation jackets for wires, cable sleeves, pipes.

Trade Names: Duraflex (Shell International Chemical Co., UK); Krene (Union Carbide, USA).

Poly(Butylene Terephthalate) (PBT). Physical properties are given in Table 8 and electrical properties in Figure 23 (see also → Polyesters).

Special properties: impact toughness, rigid, maintains shape, scratch-resistant, good slip and abrasion behavior, electrical properties are essentially frequency- and temperature-independent.

Uses: electrical insulation in household equipment, relay capstans, connecting cable, components for switches, sparking plug cases.

Trade Names: Hostadur (Hoechst, FRG); Pocan (Bayer, FRG); Vestodur (Hüls, FRG); Ultradur (BASF, FRG); Celanex (Celanese Engineering Resins, USA); Novadur (Mitsubishi Chemical Industries, Japan).

Polycarbonate (PC). Physical properties are given in Table 8 and electrical properties in Figure 24 (see also → Polycarbonates).

Special properties: low combustion, rigid elastic, high impact toughness above 90 °C, long term stability at high temperature, limited suitability under abrasive conditions, electrical properties practically independent of humidity.

Uses: moldings, casings, appliances, relay elements, condenser housings, plug connections, high-voltage insulation, cable distribution panels, mounting boards, screens, compact discs, information storage media.

Trade Names: Makrolon (Bayer, FRG); Orgallan (Atochem, France); Merlon (Mobay Chemical Corp., USA); Lexan (General Electric, USA); Jupilon (Mitsubishi Gas Chem, Japan); Sinvet (EniChem, Italy).

Polycarbonate Alloy (PC – ABS). Physical properties are given in Table 8 and electrical properties in Figure 25.

Figure 25. Relief diagram of electrical properties of polycarbonate alloy (PC – ABS)

Special properties: resistant to combustion, rigid elastic, tough above 90 °C, long term stability at high temperatures, limited suitability under abrasive conditions, electrical characteristics practically independent of humidity.

Figure 26. Relief diagram of electrical properties of polycarbonate alloy (PC – PBTP)

Figure 27. Relief diagram of electrical properties of polyethylene

Uses: moldings, casings, appliances, relay elements, condensor housings, plug connections, high-voltage insulation, cable distribution panels, mounting boards, screens.
Trade Names: Cycolac (Borg Warner Chemicals, USA); Bayblend (Bayer, FRG); Cycoloy (Borg Warner Chemicals, USA).

Polycarbonate Alloy (PC – PBTP). Physical properties are given in Table 8 and electrical properties in Figure 26.

Special properties: resistant to combustion, rigid elastic, tough above 90 °C, long term stability at high temperatures, limited suitability under abrasive conditions, electrical characteristics practically independent of humidity.

Uses: moldings, casings, consumer equipment, relay elements, condensor housings, plug connections, high voltage insulation, cable distribution panels, mounting boards, screens.
Trade Names: Makroblend (Bayer, FRG); Xenoy (General Electric, USA).

Polyethylene. Physical properties are given in Table 8 and electrical properties in Figure 27 (see also → Polyolefins).

Special properties: resistant to water, saline solutions, alkalis, acids, (exception: strong oxidizing agents), can be subjected to high mechanical stress, hard, resistant to low temperatures.

Uses: insulation and sleeve materials for cables, pipes, with 30 % carbon black deflects lines of force in conductors, transformers, etc.
Trade Names: Lupolen (BASF, FRG); Carlona (Shell International Chemical Co., UK); Alathone (Du Pont, USA); Novatec (Mitsubishi Chemical Industries, Japan); Dylan (Arco Chemical Co., USA).

Cross-linked Polyethylene. Physical properties are given in Table 8 and electrical properties in Figure 28.

Figure 28. Relief diagram of electrical properties of cross-linked polyethylene

Special properties: stable at high temperature, high impact strength at low temperature, resistant to stress cracking, greater resistance to elevated temperatures than polyethylene.

Uses: insulation and sleeve materials for cables, shrinkable sleeves.
Trade Names: Lubonyl (N. Lundbergs Fabrics AB, Sweden); Alveolit (Sekisui Chemical Co., Japan); Alveolux (Alveo AG, Switzerland); Blanex (Reichhold Chemicals Inc., USA); Elapor (Elastogran, FRG).

Polyetherimide. Physical properties are given in Table 8 and electrical properties in Figure 29 (see also → Polymers, High-Temperature).

Figure 29. Relief diagram of electrical properties of polyetherimide

Special properties: transparent yellow; high heat resistance; very high resistance to combustion; resistant to alcohols; fuels; lubricants; detergents, acids and weak alkalis; resistant to UV light, high energy sources of radiation, hydrolysis, hot water, and steam.

Uses: casings, equipment, protective relays for high-voltage supplies, multiple connecting plugs, soldered connecting cables, components for integrated circuits.

Trade Names: Ultem (General Electric Co., USA).

Polyethersulfone. Physical properties are given in Table 8 and electrical properties in Figure 30 (see also → Polymers, High-Temperature).

Figure 30. Relief diagram of electrical properties of polyethersulfone

Special properties: transparent yellow, high long-term stability, low tracking propensity until the glass transition temperature is approached, resistant to acids and alkalis, not susceptible to hydrolysis, resistant to oxidation, highly incombustible, dielectric values essentially temperature- and frequency-independent.

Uses: involving high demands in electrical engineering, insulation films.

Trade Names: Udel (Amaco Chemicals, USA); Ultrason (BASF, FRG); Victrex (ICI, UK).

Poly(Ethylene Terephthalate). Physical properties are given in Table 8 and electrical properties in Figure 31 (see also → Polyesters).

Figure 31. Relief diagram of electrical properties of poly-(ethylene terephthalate)

Special properties: tough, stiff, maintains shape at high temperature, good slip and abrasion behavior, electrical properties are only slightly temperature- and frequency-dependent.

Uses: insulation and sleeve materials for cables, sonic substrates, insulation materials, insulation films.

Trade Names: Hostaphan (Hoechst, FRG); Crastin (Ciba-Geigy, Switzerland); Melinar (ICI, UK); Rynite (Du Pont, USA).

Polyimide. Physical properties are given in Table 8 and electrical properties in Figure 32 (see also → Polyimides).

Special properties: high thermal stability, resistant to most dilute or weak acids, attacked by strong alkalis and ammonia, permanent humidity may cause cracking, pronounced resistance to high-energy radiation.

Uses: electrical and electronic components, films, shrinkage films.

Figure 32. Relief diagram of electrical properties of polyimide

Figure 33. Relief diagram of electrical properties of poly(methyl methacrylate)

Figure 34. Relief diagram of electrical properties of poly(4-methyl-1-pentene)

Figure 35. Relief diagram of electrical properties of polyoxymethylene

Trade Names: Kapton, Vespel (Du Pont, USA); Kinel (Rhône-Poulenc Specialities Chimiques, France).

Poly(Methyl Methacrylate). Physical properties are given in Table 8 and electrical properties in Figure 33 (see also → Polymethacrylates).

Special properties: hard, tough, highly transparent, weather-resistant, chemically inert to medium concentrations of acids, resistant to fuels, physiologically inert.

Uses: lamps, traffic lights, nautical aids, optical fibers, high-pressure mercury lamps, optical data storage media.

Trade Names: Lucite (Du Pont, USA); Plexiglas (Röhm, FRG); Altulite (Altulor Groupe CdF Chimie, France); Sumipex (Sumitomo Chemical Co., Japan).

Poly(4-methyl-1-pentene) (PMP). Physical properties are given in Table 8 and electrical properties in Figure 34 (see also → Polyolefins).

Special properties: light weight, crystal clear, rigid, not suitable for exterior applications, good thermal stability.

Uses: insulation for coaxial and electrical cables.

Trade Names: TPX (Mitsubishi Petrochemical Co., Japan).

Polyoxymethylene (POM). Physical properties are given in Table 8 and electrical properties in Figure 35 (see also → Polyoxymethylenes).

Special properties: high strength and stiffness, high dynamic loading capacity over a wide temperature range, high impact toughness even at −40 °C, high surface hardness, low coefficient of friction, good wear properties, low gas permeability, not resistant to UV light, physiologically

Figure 36. Relief diagram of electrical properties of polypropylene

Figure 37. Relief diagram of electrical properties of poly(phenylene oxide)

inert, dielectric characteristics are practically independent of frequency and temperature.

Uses: precision components for measuring instruments in electronics and precision engineering, household appliances.

Trade Names: Delrin (Du Pont, USA); Ultraform (BASF, FRG); Tenac (Asahi Chemical Industries, Japan).

Polypropylene. Physical properties are given in Table 8 and electrical properties in Figure 36 (see also → Polyolefins).

Special properties: stiff, impact toughness, no stress cracking, resistant to hot water and chemicals.

Uses: accumulator boxes, casings for electrotechnical equipment, electrotechnical components.

Trade Names: Vestolen P (Hüls, FRG); Hostalen PP (Hoechst, FRG); Propathene (ICI, UK); Profax (Himont, USA); Noblen (Mitsubishi Petrochemical Co., Japan).

Poly(Phenylene Oxide). Physical properties are given in Table 8 and electrical properties in Figure 37 [see also → Poly(Phenylene Oxides)].

Special properties: high long-term stability; low tendency to tracking until the glass transition temperature is approached; resistant to acids, alkalis, hydrolysis, and oxidation; highly incombustible; transparent.

Uses: cable insulation for data processing equipment and equipment for telecommunications.

Trade Names: Luranyl (BASF, FRG); Noryl (General Electric, USA); Vestoran (Hüls, FRG).

Poly(Phenylene Sulfide). Physical properties are given in Table 8 and electrical properties in Figure 38.

Figure 38. Relief diagram of electrical properties of poly(phenylene sulfide)

Special properties: transparent, requires special reinforcement, low glass transition temperature, high thermal loading capacity, dielectric properties essentially independent of temperature and frequency.

Uses: encapsulation of electronic components, insulating films.

Trade Names: Ryton (Phillips Petroleum Chemicals, Belgium).

Polystyrene. Physical properties are given in Table 8 and electrical properties in Figure 39 (see also → Polystyrene and Styrene Copolymers).

Figure 39. Relief diagram of electrical properties of polystyrene

Figure 40. Relief diagram of electrical properties of polysulfone

Figure 41. Relief diagram of electrical properties of polytetrafluoroethylene

Figure 42. Relief diagram of electrical properties of poly(vinyl chloride)

Special properties: crystal clear; high gloss; brittle; resistant to humidity, salt solutions, alkali and nonoxidizing acids; mechanical properties only slightly time- and temperature-dependent; dielectric properties are independent of temperature and frequency; susceptible to damage by UV light.

Uses: encapsulation of electronic components, insulating films, dielectric for capacitors.
Trade Names: Styroflex (Norddeutsche Seekabelwerke AG, FRG); Vestyron (Hüls, FRG); Sternite (Chemical Products, UK); Dylene (Arco Chemical Co., USA); Esbrite (Sumitomo, Japan); Toporex (Mitsui Toatsu Chemicals, Japan).

Polysulfone. Physical properties are given in Table 8 and electrical properties in Figure 40 (see also → Polymers, High-Temperature).

Special properties: transparent yellow; high mechanical loading capacity; dielectric properties only slightly temperature- and frequency-dependent, resistant to acids, bases, oxidation and hydrolysis; highly incombustible.

Uses: insulation films, circuit boards.
Trade Name: Ultrason (BASF, FRG).

Polytetrafluoroethylene. Physical properties are given in Table 8 and electrical properties in Figure 41 (see also → Fluoropolymers, Organic, Chap. 2.2.).

Special properties: difficult to wet; antiadhesive; favorable coefficient of friction; noncombustible; weather-resistant; physiologically inert; extremely resistant to corrosion, solvents, acids, and bases; dielectric properties independent of temperature and frequency.

Uses: films, insulation, insulating and sleeve material in cables.
Trade Names: Hostaflon TF (Hoechst, FRG); Teflon (Du Pont, USA); Polyflon (Daikin Kogyo Co., Japan); Fluon (ICI, UK).

Poly(Vinyl Chloride). Physical properties are given in Table 8 and electrical properties in Figure 42 [see also → Poly(Vinyl Chloride)].

Special properties: highly incombustible, rigid, weldable, thermoformable, resistant to salt solutions, bases, most acids, and fuels.

Uses: insulation, casings, appliance components, insulating and sleeve material in cables.
Trade Names: Vestolit (Hüls, FRG); Trosiplast (Hüls-Troisdorf, FRG); Vinoflex (BASF, FRG); Duval (Alpha Chemical & Plastics Corp., USA); Corvic (ICI, UK); Nipolit (Chisso Corp., Japan).

Styrene – Acrylonitrile Copolymer. Physical properties are given in Table 8 and electrical properties in Figure 43 (see also → Polystyrene and Styrene Copolymers).

Figure 43. Relief diagram of electrical properties of styrene – acrylonitrile copolymer

Special properties: resistant to UV light, weather-resistant, good long-term stability at elevated temperature, good formability.

Uses: insulators, insulation material, ventilators, casings for electrical equipment, electrical, electronic, telecommunications, protectively insulated components.
Trade Names: Acrylafil (Fiberfil Inc., USA); Thermocomp (LNP Corp., USA); Luran (BASF, FRG); Lustran (Monsanto Co., USA); Litac (Mitsui Toatsu Chemicals Inc., Japan).

Styrene – Butadiene Copolymer. Physical properties are given in Table 8 and electrical properties in Figure 44 (see also → Polystyrene and Styrene Copolymers).

Figure 44. Relief diagram of electrical properties of styrene – butadiene copolymer

Special properties: impact toughness, long-term thermal stability, good formability, limited resistance to UV light.

Uses: casings for office equipment, electrical, electronic, telecommunications, protectively insulated components.
Trade Names: Superflex (Carl Gordon Ind., USA).

3.2.2. Thermosets

Thermosets are curable synthetic resins and polymers that undergo irreversible cross-linking and become insoluble on heating within a certain temperature range or on addition of catalysts.

The term also includes cured products which do not change significantly below their decomposition temperature. Thermosets can be modified with fillers. Physical properties are compiled in Table 9.

Epoxy Resins. Physical properties are given in Table 9 and electrical properties in Figure 45 (see also → Epoxy Resins).

Special properties: strong adhesion to metals, good flow properties, no material losses, thermally stable, light colors.

Uses: jacketing, contact substrates in electrical applications, insulation of converters, substrate material for motor armatures, collector rings in electrical motors and generators.
Trade Names: Beckopox (Hoechst, FRG); Araldit (Ciba-Geigy, Switzerland); Epodite (Showa High Polymer Co., Japan); Epocast (M

Table 9. Physical properties of thermosets

Polymer	Density, g/cm^3	Tensile strength, N/mm^2	Ultimate strain, %	Long-term thermal stability, °C
Epoxy Resins (EP)	1.2	60	4	150
Melamine – formaldehyde resins (MF)	1.5	30	1	65 – 100
Phenol – formaldehyde resins (PF)	1.5	25	1	150
Synthetic resin (chip board)	1.2	130	5	100
Polyurethane (PUR)	1.3	45	50	80
Silicone resin (SI)	1.6	90	2	180
Urea – formaldehyde resins (UF)	1.5	30	1	120
Unsaturated polyester (UP)	1.2	60	2	70

Figure 45. Relief diagram of electrical properties of epoxy resins

Figure 46. Relief diagram of electrical properties of melamine – formaldehyde resins

& T Chemicals Inc., USA); Epikote (Shell International Chemical Co., UK).

Melamine – Formaldehyde Resins. Physical properties are given in Table 9 and electrical properties in Figure 46 (see also → Amino Resins).

Special properties: flame resistant; high mechanical loading capacity; resistant to fuels, oils, solvents, alcohols; low stability to acids and bases; prone to stress cracking; can be dyed with light colors.

Uses: electrical installations, electrical components, fuse elements.

Trade Names: Ultrapas (Hüls-Troisdorf, FRG); Tufnol (Tufnol Ltd., UK); Textolite (General Electric, USA); Synthane (Synthane-Taylor Corp., USA); Nikamelamine (Nippon Carbide Ind., Japan).

Phenol – Formaldehyde Resins. Physical properties are given in Table 9 and electrical properties in Figure 47 (see also → Amino Resins).

Figure 47. Relief diagram of electrical properties of phenol – formaldehyde resins

Special properties: insensitive to heat and humidity, thermally stable, dimensionally stable, only dark colors.

Uses: insulating material, casings for electrical and electronic applications.

Trade Names: Acell (BP Chemicals, UK); Alveophen (Synthetic Resins Ltd., UK); Bakelite (Bakelite, FRG); Compolet (Nobel In-

dustries Sweden, Sweden); Dynapor (Hüls-Troisdorf, FRG).

Synthetic Resin – Chip Board. Physical properties are given in Table 9 and electrical properties in Figure 48.

Figure 48. Relief diagram of electrical properties of synthetic resin – chip board

Special properties: properties are mostly those of the impregnating agent.

Uses: high-voltage insulation, slot liners.

Trade Names: Delignit (Blomberger Holzindustrie, FRG); Pag-Holz (Pag-Preßwerk, FRG).

Polyurethane. Physical properties are given in Table 9 and electrical properties in Figure 49 (see also → Polyurethanes).

Figure 49. Relief diagram of electrical properties of polyurethane

Special properties: constant mechanical behavior over a wide temperature range; resistant to surface and sea water; resistant to biological contamination; limited resistance to hydrolysis by steam, hot water, acids and bases; physiologically inert when completely cross-linked; castable; curing takes place even at low temperature.

Uses: cable end caps, converters, transformers, ignition coils.

Trade Names: Elastan (Elastogran, FRG); Desmodur (Bayer, FRG); Suprasec (Polyurethanes Group ICI, UK).

Silicone Resin. Physical properties are given in Table 9 and electrical properties in Figure 50 (see also → Silicones).

Figure 50. Relief diagram of electrical properties of silicone resin

Special properties: chemically inert, physiologically inert, water-repellent, physical and electrical properties remain almost unchanged from very low to high temperatures.

Uses: thermally stable impregnating resins.

Trade Names: Baysilon (Bayer, FRG); Wacker Silicone (Wacker Chemie, FRG); GE-Silicone (General Electric, USA); DC-Silicone (Dow Corning Corp., USA).

Urea – Formaldehyde Resins. Physical properties are given in Table 9 and electrical properties in Figure 51 (see also → Amino Resins).

Special properties: stable to light, resistant to solvents and oils, but not to acids and bases, light colors possible.

Uses: electrical installations.

Trade Names: Pollopas (Hüls-Troisdorf, FRG); Beetle, Scarab (BIP Chemicals, UK); Urochem (Chemiplastica S.p.A., Italy).

Unsaturated Polyester. Physical properties are given in Table 9 and electrical properties in Figure 52 (see also → Polyester Resins, Unsaturated).

Figure 51. Relief diagram of electrical properties of urea–formaldehyde resins

Figure 52. Relief diagram of electrical properties of unsaturated polyester

Special properties: meltable, can be cast when liquid, no material losses, dimensionally stable, not prone to stress cracking, stable to light, easy to process.

Uses: mounting electrical components, also for high-voltage applications.

Trade Names: Palatal (BASF, FRG); Vestopal (Hüls, FRG); Alpolit (Hoechst, FRG); Crystic (Scott Bader Co., UK); Glastic (Glastic Corp., USA); U-Pica (Japan-Upica, Japan).

3.2.3. Elastomers

Elastomers are natural or synthetic polymers (→ Rubber, 2. Natural; → Rubber 3., Synthetic) which exhibit rubberlike behavior between at least 20 °C and their respective decomposition temperature. They solidify at or below 0 °C. The rubber – elastic behavior is a result of the tangled arrangement of the molecular chains or of their degree of cross-linking. Physical properties of elastomers are compiled in Table 10.

Chloroprene Rubber. Physical properties are given in Table 10 and electrical properties in Figure 53.

Figure 53. Relief diagram of electrical properties of chloroprene rubber

Special properties: highly incombustible, leatherlike toughness, weather-resistant, corrosion-resistant.

Uses: insulating and sleeve material for cables.

Trade Names: Baypren (Bayer, FRG); Butaclor (Rhône-Poulenc Specialities Chimiques, France); Neoprene (Du Pont, USA).

Ethylene – Propylene Terpolymer. Physical properties are given in Table 10 and electrical properties in Figure 54.

Special properties: rubber-elastic, abrasion resistant, stable towards aging and weathering (oxygen, ozone, water, UV radiation, high temperature), inert towards many chemicals.

Uses: insulation and sleeve material for cables, plugs, cable filling, with carbon black causes deflection of the lines of force in conductors, transformers, etc.

Table 10. Physical properties of elastomers

Polymer	Density, g/cm^3	Tensile strength, N/mm^2	Ultimate strain, %	Long-term thermal stability, °C
Chloroprene rubber (CR)	1.3 – 1.7	55	250	60 – 90
Ethylene – propylene – terpolymer (EPM – EPDM)	0.9	18	380	140
Ethylene – propylene rubber (EPR)	1.3	4	200	90
Ethylene – vinyl acetate rubber (EVA)	1.4	7	200	120
Styrene – butadiene rubber (SBR)	0.94	5 – 25	500	70
Silicone rubber (SI-R)	1.3	4 – 9	300 – 700	200

Figure 54. Relief diagram of electrical properties of ethylene – propylene terpolymer

Figure 55. Relief diagram of electrical properties of ethylene – propylene rubber

Figure 56. Relief diagram of electrical properties of ethylene – vinyl acetate rubber

Figure 57. Relief diagram of electrical properties of styrene – butadiene rubber

Trade Names: Buna AP (Hüls, FRG); Vistalon (Exxon Chemical Co., USA).

Ethylene – Propylene Rubber. Physical properties are given in Table 10 and electrical properties in Figure 55.

Special properties: resistant to chemicals, ozone, aging, water, acids, and alkalis; weather resistant; unstable to mineral oils and organic solvents.

Uses: insulating and sleeve material for cables.

Trade Names: Dutral TP (Montepolmeri, Italy); Intolan (Dow Corning Corp., USA); Vistalon (Exxon Chemical Co., USA).

Ethylene – Vinyl Acetate Rubber. Physical properties are given in Table 10 and electrical properties in Figure 56. Special properties: ther-

mally stable, excellent adhesion, rubber-elastic, impact resistant.

Uses: insulating and sleeve material for cables.

Trade Name: Levapren (Bayer, FRG).

Styrene – Butadiene Rubber. Physical properties are given in Table 10 and electrical properties in Figure 57.

Special properties: resistant to organic solvents, weldable, limited stability fuels, oils, acids, and alkalis.

Uses: insulating and sleeve material for cables, capacitor components, accumulator boxes components for telecommunications, connectors, insulators.

Trade Name: Buna-Hüls (Hüls, FRG).

Silicone Rubber. Physical properties are given in Table 10 and electrical properties in Figure 58.

Figure 58. Relief diagram of electrical properties of silicone rubber

Special properties: difficult to wet, physiologically safe, electrical characteristics show little change over large regions.

Uses: insulating and sleeve material for cables, electric insulation, casting resins.

Trade Names: Silastic (Dow Corning Corp., USA); Silopren (Bayer, FRG); Wacker-Silicongummi (Wacker-Chemie, FRG).

3.2.4. Polymer Processing

Once polymeric materials have been synthesized and, if necessary, treated with fillers, pigments, plasticizers, processing aids, and agents to minimize aging and flammability, they are processed into powders or granulates. Subsequent forming operations result in products that frequently do not require further physical modification. The forming procedures most applicable to single items or small numbers of insulators include reshaping and bonding, for example by heat sealing. Thermoplastic materials can also be machined, including boring and cutting. A molded polymeric insulator, fashioned to the proper shape in a single operation without recourse to subsequent machining, may often replace conventional insulators consisting of multiple parts, each requiring its own series of machining operations. However, the equipment required to produce complicated polymeric objects are usually quite expensive, so economic factors tend to limit this approach to mass-produced items. For a more detailed description of the techniques described below see → Plastics, Processing.

Casting without the Use of Pressure. Certain polymeric materials can be formed without the use of pressure by methods such as the rotational casting of hollow objects in heated forms and centrifugal casting. Such materials include thermoplastic polymers such as poly(methyl methacrylate), polyamide 6, poly(vinyl chloride) mixed with liquid plasticizers, certain elastomers, and thermosetting polymers (casting resins, e.g., epoxy resins and polyurethanes).

Powder Techniques. The powder method entails fusing a low-melting polymer powder to a heated metal surface, for example by whirl sintering. This approach lends itself to materials such as polyolefins, cellulose acetobutyrate, and casting resins.

Low-Pressure Casting. Low-pressure casting is appropriate for polymers reinforced with glass or carbon fibers. The precursors are resin mats and prepregs made from unsaturated polyesters, epoxides, and other casting resins. These are converted to their final form either by the hand lay-up or the plane-type press process. A mixture of resin and fibers can also be sprayed at low pressure.

Casting under Thermoplastic Conditions. The thermoplastic casting method plays an important role in polymer processing. It requires a temperature in the range of 150 – 250 °C and a pressure of several hundred bar.

Calendering denotes the process of rolling a polymeric mass in the plastic state until it reaches a desired thickness, usually 0.06–0.6 mm.

Extruding. The most versatile of the processes used for forming thermoplastic materials is extrusion with a continuous screw extruder. Proper choice of dies permits the manufacture of films, pipes, tubes, sheets, slabs, and even items of more complex cross-sectional shape. Screw extruders are often coupled with calibration devices, smoothing rolls, and cooling facilities. With this approach it is possible to completely surround a metallic wire, conductor, or cable with a sprayed plastic insulator.

Pressing. Thermosetting laminates (e.g., laminated paper, glass–fabric laminates, cotton laminates, melamine–formaldehyde laminates, or phenolformaldehyde–fiberglass fabrics) are prepared with the aid of a multiplaten press in which the carrier sheet is continuously soaked with a resin solution. Suitably sized pieces of the material are then stacked in layers and warmed under pressure in a heated press, causing the resin to flow and subsequently solidify. Provided the material is cooled while still under pressure, such a press can also be used to produce thermoplastic blocks of any desired thickness with a high-quality surface finish.

Injection Molding. Injection molding machines operate on the batch principle. A heated injection cylinder operates in tandem with a completely closed forming die, the two units being separated spatially. Plastic material is introduced in portions into the die through a nozzle. Once the substance has hardened, the die is opened and the molded object ejected. The injection molding process is also applicable to thermosetting polymers.

Compression molding requires continuous heating of the forming die. Appropriate amounts of a preheated thermosetting material are first introduced into an open die. Once the die is closed, heat and pressure cause the polymer to flow and expand, entirely filling the available space. After curing is complete, the die is opened and the finished product is ejected while still hot.

Transfer Molding. In transfer molding the polymer is warmed to a plastic state in a separate compartment prior to being forced into a forming die.

Reshaping of a semifinished thermoplastic polymer into a thermoelastic state requires relatively little applied force. Cut sheets or blocks of material are brought to working temperature with the aid of infrared radiation and then drawn into monolithic forming dies where they acquire the desired shape. Finished parts are ejected after cooling.

Heat sealing complements the technique of molding. Small numbers of complex objects can be economically assembled from components by heat-sealing either with the aid of warm air or by techniques based on high-frequency radiation, heat impulses, or ultrasonics.

Soaking is especially suitable for coating electronic products with casting resins. However, it may also be utilized with insulating liquids and certain thermoplastic materials, where the latter are either preheated or applied as low-viscosity solutions. The purpose of soaking is to reduce the risk of short circuiting, for example in the windings of a current-carrying metallic conductor, by ensuring that all gaps are filled. Improved heat transfer is achieved simultaneously (the specific thermal conductivity of air is $0.026\,\mathrm{W\,m^{-1}\,K^{-1}}$, while that of synthetic resin filler is $0.6\,\mathrm{W\,m^{-1}\,K^{-1}}$). The most common soaking resins are solvent-free unsaturated polyester resins, which may be cured by activation with a setting agent. Resins generally have a higher filling power than impregnating varnishes.

Impregnation provides almost total protection against undesired environmental influences. It also confers increased mechanical stability and protection against the adverse effects of motion. Impregnation itself is normally carried out under vacuum. Most impregnating agents are liquid in the working state, but they can be transformed into a thermosetting state by curing. The method is also applicable to solvent-free trickling resins prepared from unsaturated polyesters. These materials break into droplets in the course of winding and revert to a gel-like state with

subsequent electrical conduction warming of the conductor. Rapid heating to the curing temperature induces such an impregnating agent finally to harden.

Varnishing. Metallic electrical conductors can also be electrically insulated with wire varnish. This method is often employed in transformers, motors, generators, relay coils, and similar devices. The applied polymer (usually a polyesterimide, polyurethane, polyamideimide, or polyhydantoin) is dissolved in an appropriate solvent, e.g., aromatic and aliphatic hydrocarbons, chlorinated hydrocarbons, aqueous alcohols. The conductor is passed several times through a varnish bath, and becomes uniformly coated. Solvent is evaporated in a radiation oven, permitting deposition and annealing of a multilayered coating graded according to hardness. Thermoplastic polycarbonate films can be obtained from solution in a fashion similar to varnish films, whereby the film is extracted from a drum after evaporation of solvent.

A more environmentally acceptable coating technique utilizes either a melt varnish of the polyesterimide type or a water-soluble wire varnish.

Embedding. Solvent-free, soaking, trickling, and casting resins are used for embedding components in electrotechnics. They protect costly components against environmental effects, provide mechanical stabilization, and prevent the formation of dangerous contacts. Reaction resins, monomers, or prepolymers are generally used that harden in the presence of suitable reactants. Most important are methyl methacrylate, unsaturated polyesters, epoxy resins, polyurethanes, modified phenolic resins, and furan resins. The cross-linkable hydrocarbons and methyl methacrylate casting resins have favorable dielectric values at high frequencies (Sections 2.6) and are therefore important for microwave technology (television, radar, dielectric warming).

3.3. Liquid Insulating Materials

In transformers, starter motors, and other electrical equipment that generate a considerable amount of heat, liquids are employed both as insulators and coolants. In cables, capacitors, and connections, insulation liquids are used as a functional component of the dielectric. In relays, they function as insulators, coolants, and extinguishers for arcing. Most liquid insulators consist of mineral oils or synthetic liquids.

Mineral oils are complex hydrocarbon mixtures that are obtained from petroleum oil by fractional distillation and refining. They combine important properties including high breakdown strength, good impregnation characteristics, and the ability to conduct large amounts of heat via convection. Mineral oils can also bind any gas produced during arcing with pronounced evaporation and decomposition. Depending upon the predominant hydrocarbon, the oils can be classified as *naphthene-* or *paraffin-based oils;* however, the transition between these groups is continuous–the *mixed petroleum oils.* The naphthene-based oils have a higher density, and a lower solidification point than the paraffin oils; their viscosity is also more temperature dependent. Since they are also more stable at low temperatures, they are preferred for devices used in the open air. They are also preferable for cable applications because paraffin oils are more prone to decomposition at high field strengths with formation of hydrogen and wax products. Decomposition can lead to partial discharges and gas inclusions, which may interact resulting in breakdown of the cable insulation (see section 2.7). Naphthene oils are also suitable for cable impregnation systems comprising oils and refined resins (e.g., collophonium) because the refined resins are incompatible with paraffin oils [47].

Insulation oils for transformers, converters, and relays are subject to standard regulations, e.g., IEC Publication 296, which only specifies minimum values for the breakdown voltage [48].

Since the electric strength of oils depends strongly on the measuring technique used (Section 2.7), breakdown behavior is characterized by the breakdown voltage determined under standardized conditions (specified electrode configuration, electrode separation, and test procedure, IEC Publication 156 [32]).

When insulation liquids simultaneously act as a coolant, they must have a low viscosity. They should be able to withstand cooling to $-30\,^{\circ}C$ without thickening. Furthermore, the oxidation and aging behavior of new oil and used oil should

be monitored during operation when the temperature is elevated and atmospheric oxygen has access to the equipment.

The viscosity of cable insulation oils varies within wide limits, ranging from low viscosity oils for oil cables to highly viscous impregnation systems for earthing and pressure cables. Furthermore, extremely viscous cable immersion systems can be prepared by addition of thickeners (natural resins, polymers).

The most important property of cable immersion systems is the dielectric loss index (see Section 2.6) which should be as low as possible because of the danger of thermal breakdown of the cable insulation at higher field strengths. The electrical strength of the impregnation system is less important because the high electrical strength of the cable insulation is a result of the combination of the multilayer insulation film (paper or polymeric) and impregnating agent; it depends upon the breakdown behavior of both components.

The viscosity and electrical properties of mineral oils used for high-tension capacitors (phase displacers) are similar to those of the cable insulation oils.

Synthetic Liquids. The drawbacks of mineral insulation oils (oxidizability, flammability, and aging with formation of detrimental decomposition products and deterioration of electrical properties) led to the development of synthetic insulation liquids with improved properties. A general advantage of synthetic insulation liquids is the fact that they can be reproducibly manufactured with identical structures and compositions [49]. They include chlorinated hydrocarbons, the most common being aromatic compounds such as chlorinated biphenols, chlorinated benzenes, and their mixtures. These noncombustible materials are known as *Ascarels.* Damage to health and the environment can result from careless handling and use of such toxic agents. Consequently, sale of Ascarel-containing products is prohibited in many countries. Closed systems (transformers, capacitors, etc.) have been exempted from these regulations.

During decomposition in electric arcs, Ascarels do not emit explosive or combustible gas mixtures provided that they contain equivalent molar amounts of chlorine and hydrogen; hydrogen chloride is then produced. The Ascarels are both chemically and thermally stable. They possess dipole character; their dielectric dissipation factor is therefore frequency- and temperature-dependent and they have a high relative permittivity ($\varepsilon_r \approx 4-6$ at 50 Hz).

Liquid fluorine compounds show excellent properties. They are noncombustible, prevent arcing, and are more thermally stable than Ascarels. They have a lower boiling point and are highly volatile. Because of their low viscosity, heat transfer properties are favorable. They have a high breakdown voltage, high volume resistivity (Section 2.2), and an essentially frequencyindependent dielectric dissipation factor.

Liquid silicones are polymeric organosilicon compounds with a highly variable degree of polymerization. Commercial silicone oils have differing viscosities, which are only slightly temperature-dependent. They combine excellent resistance to low temperatures (setting point $-5\,°C$ to $-80\,°C$) with outstanding high temperature stability ($240\,°C$) and are not prone to oxidation. They remain noncombustible up to operating temperatures of $300\,°C$. Silicone oils have a high breakdown strength, low dielectric dissipation factor ($\leq 1\times10^{-4}$), low relative permittivity (2.5 – 2.9), and an average volume resistivity ($10^{12}\,\Omega m$). The low temperature dependence of the dielectric dissipation factor (3×10^{-4}) is remarkable.

Other Liquid Insulators. Apart from the Ascarels and liquid silicones, further synthetic insulation fluids find application mostly in transformers, capacitors, and cables. The most important commercially available examples include compounds based on alkyl benzenes, polybutene, diarylalkanes, esters, alkyl diphenyl ethers, and high molecular mass paraffin hydrocarbons. These liquids match the excellent electrical properties of the Ascarels but not their flame retardation. They differ according to application regarding relative permittivity, dielectric dissipation factor, ignition temperature, viscosity, and the behavior toward low temperatures.

4. Selection of an Insulating Material

Within its technical committee 15 for "Insulating Materials", the International Electrotechnical Commission (IEC) has installed two subcommittees: subcommittee 15 A for "Short

Term Tests" and subcommittee 15 B for "Endurance Tests". Electrical testing methods for insulation materials are developed in the working groups of these subcommittees. The recommendations of national electrotechnical commissions serve as the basis for their development.

The intention and objective of the IEC is that the international standards drawn up by numerous experts from the member states should be adopted as the national standards. All published results should then be comparable.

The values of electrical properties given in this publication have been extracted from numerous sources; some have been supplemented and amended using the results of our own investigations. In the available literature, detailed information pertaining to testing conditions has often been omitted, consequently the data plots provide nothing more than rough guides. This can only be improved by testing identical samples of the huge range of insulating materials used in the electrotechnics industry in one and the same laboratory, under identical testing conditions that strictly comply with the international regulations. Although this undertaking would be highly desirable, it is almost impossible.

To solve a specific insulation problem, materials can be preselected from the relief diagrams. The manufacturers must then be consulted, or reference to technical data sheets can be made. Measurements or the results of an independent testing institute ensure that the material is able to meet the requirements.

What makes an outstanding material for electrical applications? The answer to this question depends upon the intended use, e.g., whether it involves low-voltage or high-tension supplies, d.c., or low-, mid-, or high-frequency sources. For applications with low-voltage supplies, the *tracking parameter* should be at least CTI 400, i.e., group II according to IEC Publication 664 [24], group I includes materials with CTI 600. Similarly, the *volume resistivity* should be greater than $10^{12}\ \Omega \cdot \mathrm{m}$, the surface resistivity at 23 °C and 50 % R.H. should be at least $10^{14}\ \Omega$.

At mains frequency, no particular demands are placed on the *dielectric dissipation factor* or the *relative permittivity* except for the application as a dielectric in capacitors. If, for example, the power loss per cubic centimeter should not exceed 0.1 W at 50 Hz and the field strength should be no greater than 1000 V/cm (see Section 2.6), then a loss index of $\varepsilon_r'' \approx 3600$ can be tolerated. An increase in the field strength to 10 000 V/cm causes a decrease in the threshold value for the loss index by a factor of 100. In the same way the loss index threshold value decreases linearly with an increase in frequency.

The magnitude of the *relative permittivity* is particularly important in determining the intended application of a material. To avoid dielectric warming, its value should be low. A lower relative permittivity is also associated with a higher breakdown voltage in air. (As a general rule, the maximum attainable breakdown voltage is achieved when the relative permittivity of the material is identical with that of the surrounding medium). For applications in capacitors, the relative permittivity should be as large as possible to minimize the geometric dimensions.

The *electrical strength* is primarily intended to allow comparison between materials. However, this is only the case when all parameters, including sample thickness, are absolutely identical. The significance of the electrical strength is thus disputable (Section 2.7). It cannot be used directly for design purposes. Test models are imperative, studies on the effect of loading time are often required.

A "single value", i.e., result at a discrete temperature and frequency does not characterize the behavior of a material under application conditions. The influences of parameters such as temperature, frequency, loading time, age, or humidity cannot be discerned from this single piece of information. A knowledge of the interdependence of the various parameters provides far more information than a single data value. In many cases, the development of technical polymers and their successful application in the electrical industry has only been possible because the complete characteristics of the material had been previously compiled and evaluated. The application range must be considered as a function of temperature, frequency, voltage, and environmental conditions. Other influences including manufacturing processes, mechanical loading, and the effects of fillers and additives are better reflected by the functions of the electrical parameters rather than by individual results at a single temperature or frequency. Automatic measurement processes have made the practical

determination of such relationships relatively inexpensive.

The following diagrams represent examples for characterizing a technical insulation material–a thermoplast with typical properties: high flame resistance, rigid-elastic, high impact toughness above 90 °C, mechanical durability at 90 °C. On the basis of the short-term electrical properties, the product quality lies within the following limits:

Tracking	CTI 250 – CTI 500
Volume resistivity	$(0.5-5)\times 10^{16}\ \Omega\cdot\mathrm{cm}$
Surface resistivity	$(0.5-5)\times 10^{15}\ \Omega$
Loss index	$(0.3-3)\times 10^{-2}$
Relative permittivity	2.9 – 3.2
Electrical strength	25 – 35 kV/mm

Figure 59 illustrates the dielectric dissipation factor (Section 2.5) and the relative permittivity (Section 2.4) as a function of temperature at frequencies of 50 Hz, 1 kHz, and 1 MHz. At temperatures below the long-term thermal stability threshold (90 °C) the curves remain relatively constant and are typical of a medium-quality material. In the vicinity of − 50 °C, a relaxation phenomenon occurs, which is indicated by the decrease in the dielectric dissipation factor at low frequencies. Above 90 °C, the dielectric dissipation factor increases sharply; the effects of conductivity losses are apparent.

Figure 59. Relative permittivity (A) and dielectric dissipation factor (B) of a thermoplast as functions of temperature a) 50 Hz; b) 1 kHz; c) 1 MHz

Figure 60 illustrates both dielectric parameters as functions of frequency. The decrease in the relative permittivity with increasing frequency is low. The relative permittivity must decrease with increasing frequency because it assumes a value equal to the square of the refractive index at the optical relative permittivity. The dielectric dissipation factor reaches a broad maximum at 10 MHz.

Figure 60. Relative permittivity (A) and dielectric dissipation factor (B) of a thermoplastic polymer blend as functions of frequency at 23 °C

Figure 61 shows the plot of volume resistivity (Section 2.2) as a function of temperature. The decrease in the volume resistivity by a factor of five powers of ten is considerable and illustrates that the number of mobile charge carriers strongly increases with increasing temperature.

Figure 61. Volume resistivity of a thermoplastic polymer blend as a function of temperature

The surface of the sample is hygroscopic. This is shown in Figure 62 by the decrease in surface resistivity with increasing air humidity (Section 2.3).

Because of the large deviation in measured values, the variation in the measurement of surface resistivity as a function of temperature (see Section 2.3) has been included in Figure 63. A pronounced decrease in resistance surprisingly

Figure 62. Surface resistivity of a thermoplastic polymer blend as a function of atmospheric humidity

Figure 63. Surface resistivity of a thermoplastic polymer blend as a function of temperature

appears at approximately 90 °C but the reason for this is not known.

The electric strength is shown as a function of temperature in Figure 64. A pronounced decrease in the breakdown voltage occurs between 90 and 100 °C. This represents the limitations in thermal stability as determined using nonelectrical procedures (see also Section 2.7).

Figure 64. Electrical strength of a thermoplastic polymer blend as a function of temperature

On the basis of the above properties, the insulating material would be suitable for applications in the low- and middle-voltage range in a normal climate (e.g., 20 °C, 55 % R.H.), and at a working temperature up to 70 °C. Small distances between conductors subjected to potential differences are possible. The material is also qualified for integrated circuits and for high frequencies. It is highly suited for applications in audio, video, and telecommunication equipment.

1. Introduction

In 1957, A. ISAACS and J. LINDENMANN observed that mammalian cells incubated with a heat-inactivated influenza virus produced a substance that could confer on fresh cells a resistance to infection by live virus [1]. This substance, called *interferon*, was subsequently shown to consist of a system of distinct proteins, many of which are structurally related, that are products of multigene families as well as separate genes [2]. Interferons (IFNs) are unique antiviral agents because they act directly on the target cell to confer a state of resistance to viral infectivity at one or more phases of the viral replication cycle, but have no direct toxicity toward the virus itself. The biological effects of IFN are not limited to antiviral activity, however: highly purified preparations of genetically engineered IFN have potent antiproliferative and immunomodulatory effects both in vitro and in animal models [3], [4]. Many types of animal cells can produce IFN in response to a variety of external stimuli or "inducers," including certain types of double-stranded ribonucleic acid (RNA), antigens, and mitogens [5].

Purification of IFN from natural sources for structural and biological characterization, as well as for initiation of clinical trials, proved difficult because IFNs exhibit a high specific biological activity and are normally produced by cells in low absolute quantities. Thus, only relatively impure preparations containing up to 1 % IFN could be partially purified from normal human leukocytes for use in clinical trials in the mid 1970s. Not until the late 1970s could sufficient quantities of naturally occurring IFNs be purified from lymphoblastoid cells for initiation of structural studies [6], [7]. However, the achievement of WEISSMANN and coworkers in cloning the gene for a single subtype of human leukocyte IFN, IFNα-2, in *Escherichia coli* allowed the preparation of gram quantities through genetic engineering [8]. The availability of vir-

10.1002/14356007.a14_365

tually unlimited quantities of IFN has permitted detailed biological and structural characterization, as well as extensive clinical trials worldwide [9], [10].

Genetically engineered IFNα-2 b (Intron A) has now been approved for marketing in over 30 countries, including the United States, for both cancer and viral indications such as hairy cell leukemia, acquired immune deficiency syndrome (AIDS)-related Kaposi's sarcoma, renal cell carcinoma, malignant melanoma, multiple myeloma, laryngeal papillomatosis, and condyloma acuminata (genital warts). Extensive clinical trials have also been performed on IFNγ [11–14] and IFNβ [15], [16]. This article reviews the properties, production, and specifications of recombinant human IFNα, for which the most data are available. However, for comparative purposes selected data are also provided for human IFNβ and IFNγ, as well as natural leukocyte IFN. For further information, see [2–4], [9], [17–44].

2. Classification and Origin

The first classification of IFN subtypes was based on the observation that exposure to pH 2 inactivated the antiviral activity of some IFN preparations. The IFN stable at pH 2 was designated class I, whereas IFN labile at pH 2 was designated class II. Thus, heterogeneity exists within the IFN system. Subsequently the type I IFNs produced by leukocytes and fibroblasts were shown to differ in their antigenicity and in selected chemical properties. As a result of this observation, type I IFNs were renamed according to the cells of origin, i.e., leukocyte and fibroblast IFN, respectively. These definitions, however, were not adequate because IFN identified as fibroblast with specific antisera was also shown to be produced by leukocytes; leukocyte IFN could likewise be produced by fibroblasts. Therefore, international agreement was reached that IFNs should be categorized as *alpha* and *beta*, depending principally on their antigenic properties. A third antigenic category, referred to as *gamma* (or *immune*) IFN, was also recognized; this IFN class is produced principally by T lymphocytes stimulated by specific antigens or mitogens and is categorized as type II (i.e., acid-labile).

In addition to viruses, a number of natural and synthetic agents are capable of inducing IFN production in a wide variety of cell types [5]. A general summary of cell types and IFN inducers for the three IFN classes is presented in Table 1. Interferon-inducing agents include bacteria, protozoa, mycoplasma, rickettsia, and bacterial products (e.g., bacterial cell wall extracts, lipopolysaccharides, and endotoxins). The effect of synthetic and natural nucleic acids and polyanions, including double-stranded RNA, synthetic polynucleotides, and synthetic polycarboxylates, has been of special interest. Low molecular mass compounds such as anthraquinones, propanediamines, acridines, pyrimidines and fluorenones can also induce IFN titers in the serum of certain animals. Specific structural requirements for these low molecular mass compounds to induce IFN have not been identified yet. Metabolic inhibitors (e.g., actinomycin D), mitogens, antigens, and tumor cells have also been identified as IFN inducers.

Table 1. Classes, sources, and inducers of IFN

Class	Cell source	Inducers
Alpha (leukocyte, type 1)	macrophages	viruses
	B cells	foreign cells and their products
	null cells ∗	low molecular mass inducers (e.g. tilorone)
Beta (fibroblast, type I)	epithelial cells	viruses
	fibroblasts	polynucleotides
	null cells ∗	foreign cells and their products
	lymphoblasts	metabolic inhibitors B-cell mitogens
Gamma (immune, type II)	T cells	T-cell mitogens
	null cells ∗	foreign antigens metabolic inhibitors

∗ Null cells are non-B, non-T lymphocytes.

3. Biological Activity

As previously noted, IFN was first discovered as an antiviral agent that could protect cells from viral infectivity. However, a variety of other biological effects can be elicited by both natural and recombinant IFNs. Utilizing relatively crude preparations, Paucker et al. [45] described the first nonantiviral activity of IFN, i.e., the ability to inhibit cell growth. Subsequently, IFN was also shown to exert potent immunomodulatory

effects as measured by its ability to enhance the activity of immune effector cells (e.g., natural killer cells) [46]. The range of biological activity demonstrated for IFN has increased considerably [47]. One of the important features of IFNs is their species specificity; all classes of human IFN are most effective on human cells and are generally much less potent on animal cells. However, because many of the early studies on nonantiviral activity were performed with impure preparations of naturally occurring IFNs, these biological effects were not known to be inherent properties of IFN. Subsequent use of highly purified recombinant IFN has demonstrated that most observed biological effects can be attributed to IFN [2], [3].

These properties of IFN provide strong support for the clinical application of this class of biological response modifiers as both antiviral and antitumor agents. Aspects of the three categories of biological activity of IFN are reviewed briefly below.

3.1. Antiviral Activity

Early studies indicated that the replication of a broad spectrum of both RNA- and DNA-containing viruses, either oncogenic or nononcogenic, could be inhibited by IFN [37]. Examples of such DNA viruses are herpes virus types 1 and 2 and cytomegalovirus. Examples of RNA viruses are rhinovirus and respiratory syncytial virus. In addition, IFNα can act synergistically with other antiviral agents [48]. However, the degree of antiviral activity depends not only on the nature of the virus, but also on the characteristics of the target cell, the type of IFN, and the ratio of infecting virus to cell number. In vivo studies in nonhuman primate models have also demonstrated the antiviral activity of IFNα and IFNβ against herpesvirus [49].

The specific antiviral activities of highly purified recombinant IFNα subtypes utilizing human foreskin fibroblast cells and encephalomyocarditis virus are summarized in Table 2 [50]. Four of these (α-1, -2, -4, and -7) are naturally occurring gene products, whereas the remaining two subtypes (δ-4 α-1 and the δ-4 α-2/α-1 hybrid) are products of recombinant DNA technology in which the first four amino acids of the amino terminus are deleted. Both of these molecules lack a cysteine residue at position 1 and, hence, are predicted to contain only one disulfide bond (see Chap. 5). The hybrid molecule consists of residues 5 – 62 of IFNα-2 and residues 64 – 166 of IFNα-1. Despite the high degree of purity of these preparations and their amino acid sequence homology (at least 70 %), the specific antiviral activities span approximately two orders of magnitude. Interferon α-2 has the highest antiviral activity (1.7×10^8 IU/mg).

Table 2. Specific antiviral activity of IFNα subtypes $*$

IFN subtype	Activity, IU/mg
α-1	7.1×10^6
α-2	1.7×10^8
α-4	1.0×10^8
α-7	2.0×10^7
δ-4 α-1	2.8×10^6
δ-4 α-2/α-1	1.0×10^8

$*$ Activity was determined by the CPE-inhibition assay employing encephalomyocarditis virus and human foreskin cells; data represent the mean of at least nine assays [50].

Interferon confers resistance to viral infectivity by affecting various stages of the viral replication cycle. It may inhibit early events (e.g., attachment, receptor-mediated endocytosis, uncoating, and transcription), the translation of messenger RNA, and virus maturation, including budding of the virion at the cell membrane. Other evidence also indicates that IFN lowers the infectivity of the progeny virions.

3.2. Anticellular Activity

Interferon can inhibit the growth of a variety of normal and malignant cells in vitro. For example, it can inhibit the growth of fresh tumor cells in the clonogenic assay [51]. This assay is an in vitro cloning technique in which cancer cells form colonies in a semisolid medium. The antigrowth activity of IFN is generally cytostatic (i.e., prevents cell division) rather than cytotoxic (i.e., kills cells directly). Sensitivity to growth inhibition by IFN is variable, even within cells of the same histologic type; this may be due to differences in IFN receptor levels or in the affinity of IFN for the receptor.

Combinations of IFN and chemotherapeutic agents may have a synergistic (enhancing) or additive interaction as antitumor agents [52], [53].

Synergy may be the result of a complex interaction of factors, including the nature of the tumor, the mechanism of action of the cytotoxic agent, and the administration schedule of IFN and the cytotoxic agent. Thus, synergistic interactions between IFN and cytotoxic drugs have been observed in the human tumor clonogenic assay utilizing recombinant IFNα and vinblastine, cisplatin, or doxorubicin [54], [55]. However, synergy is highly schedule-dependent. When cells were first treated with IFN

α followed by doxorubicin or vice versa, no synergy was observed. In contrast, dramatic synergy was observed when both agents were administered simultaneously. Other drugs tested in this assay (e.g., bleomycin, methotrexate, or vinca alkaloids) were not synergistic with IFNα. The mechanism of the observed synergy as well as of drug failure remains unknown.

Another important aspect of the anticellular activity of IFNα is its ability to modulate the state of cellular differentiation. Both inhibition and acceleration of differentiation have been observed [56]. Interferon also interacts synergistically with other agents that inhibit differentiation, e.g., phorbol ester tumor promoters [57]. The induction of differentiation in tumor cells mediated by IFN may account for at least a part of its antitumor activity because the degree of cellular differentiation appears to be inversely related to the rate of cell division.

3.3. Immunomodulatory Activity

A variety of immune functions can be affected by IFN [41]. Immune response may be mediated either by cells or by antibodies. Interferon can activate or inhibit both cellular and humoral (antibody) immune function: higher concentrations generally inhibit, whereas lower concentrations activate. Natural killer cell activity as well as macrophage tumoricidal and tumoristatic activities can be significantly enhanced by both IFNα and IFNγ. Other types of immune effector cells activated by IFN include cytotoxic T lymphocytes, cells involved in antibody-dependent cytotoxicity, and mast cells. Interferons of all three types induce expression of class I antigens of the major histocompatibility complex (MHC), and IFNγ induces expression of class II MHC antigens. This property is significant because class I MHC antigens play a role in the lysis of virus-infected cells and tumor cells by cytotoxic T lymphocytes. Class II MHC antigens are essential for the ability of macrophages to function as antigen-presenting cells. However, both classes of MHC antigens are fundamentally important for achieving maximal immune responsiveness. All types of IFN appear to inhibit antibody production, although under certain conditions of dosing and time of addition, an enhancement of antibody production has been observed.

The role of immune stimulation in clinical responses to IFN remains unknown. For example, measurements of natural killer cell activity after administration of recombinant IFNα have demonstrated both enhancement and depression of activity, as well as no response [58], [59]. However, stimulation by IFN of cytotoxic effector cell function and antibody production may still represent major mechanisms of its therapeutic activity.

4. Mechanism of Action

The first step in expression of the biological activity of IFN is its binding to specific cell surface receptors [60]. The number of receptors for IFNα on human cells is reported to be ca. 650 – 13 000 per cell. The ligand and receptor form a high-affinity complex with a dissociation constant of 10^{-10} – 10^{-11} mol/L. The IFN-receptor complex has an apparent molecular mass of 140 000 – 150 000 deduced from chemical cross-linking of radioactively labeled IFN to the cell surface. Thus, the apparent molecular mass of the receptor is 120 000 – 130 000 if one molecule of IFN is bound per receptor. The failure of certain cells to respond to IFN may be due to absence of the receptor or a low affinity of IFN for the receptor.

Ultrastructural studies indicate that bound IFNα enters cells by a clustering of the receptor – ligand complex into "coated pits." These pits, which are surrounded by the protein clathrin, function in the transport of a variety of molecules into the cell. The pits pinch off to form vesicles (so-called receptosomes), which can transport their contents to a variety of targets within the cell. The role of internalization of IFNα into the cell in the mechanism of action is

yet to be elucidated. Interferon alone, the IFN–receptor complex, or IFN degradation products may trigger a biological response; alternatively, binding of IFN to the cell surface may itself be sufficient.

Binding of IFNα to its receptor induces the synthesis of about a dozen different proteins ranging from 15 000 to 120 000 in molecular mass. Many of these have not been identified, and their role in the mechanism of IFN activity is unknown. Interferon also affects the activity of specific proteins or enzymes. For example, levels of ornithine decarboxylase and *S*-adenosylmethionine decarboxylase, enzymes involved in polyamine biosynthesis, are reduced by IFN treatment [61]. Because these enzymes are critical for cellular proliferation, their inhibition may account for the antigrowth activity of IFN. Interferon treatment can increase cyclic guanosine 5′-monophosphate (cGMP) and cyclic adenosine 5′-monophosphate (cAMP); both of these compounds have also been implicated in growth regulation [61]. However, the exact biochemical mechanism for the antiproliferative effects of IFN remains unknown.

As noted above, all three IFN classes can induce the expression of class I MHC antigens [62], which mediate the lysis of virus-infected cells and tumor cells by cytotoxic T lymphocytes. In addition, IFN can enhance the expression of the immunoglobulin G receptor on lymphocytes and macrophages; this, in turn, may enhance antibody-dependent cytotoxicity or macrophage-mediated phagocytosis [63].

An extensively characterized enzyme that is induced by IFN treatment and appears to play a critical role in interferon's antiviral and antiproliferative activities is 2′,5′-oligoadenylate synthetase (E. C. 2.7.7.-) [64]. This enzyme catalyzes the synthesis of a family of novel 2′,5′-oligoadenylate nucleotides that regulate the breakdown of RNA in cells. Reported levels of induction of the synthetase vary between 10- and 10 000-fold. The enzyme requires double-stranded RNA, which may be produced by the virus as a replicative intermediate, for expression of enzyme activity. Although the exact mechanism for this activation is not known, the double-stranded RNA may bind to the enzyme and convert it to its biologically active form. The 2′,5′-oligoadenylates activate a latent endoribonuclease, known as RNase L, which catalyzes the cleavage of both messenger and ribosomal RNA. Thus, the localized activation of endonuclease by double-stranded RNA present during viral replication may account for the selective cleavage of viral versus host RNA.

Interferon induces another system that also requires double-stranded RNA for activation, namely, a protein kinase that catalyzes the phosphorylation of protein initiation factor eIF-2, as well as the ribosomal protein P 1 [65]. In cell-free systems, the kinase is activated by much lower concentrations of double-stranded RNA than is 2′,5′-oligoadenylate synthetase; higher concentrations of double-stranded RNA inhibit the kinase but activate the synthetase. Thus, the level of double-stranded RNA may determine which biochemical pathway is important in the expression of antiviral activity.

5. Physicochemical Properties

Only very low (picogram) quantities of IFN can normally be produced from natural sources because the biological activity is expressed at very low protein levels. Thus, characterization of its properties was for many years slow and incomplete. Studies on IFNα prepared from a variety of natural sources, including virally induced natural leukocytes, lymphoblastoid cells, and chronic myelogenous leukemic cells, suggested that IFNα consists of a family of multiple species with apparent molecular masses determined by sodium dodecyl sulfate – polyacrylamide gel electrophoresis (SDS – PAGE), ranging from 16 000 to 27 000. Amino acid analysis of the purified proteins indicated that their compositions were similar but that IFNα consisted of a family of proteins with different amino acid sequences. However, further characterization of the physicochemical properties of IFNs was severely hindered by the fact that IFNs purified from natural sources were frequently contaminated with other proteins and IFN subtypes. In addition, the extremely low levels of substance produced resulted in large losses of protein because of adsorption and surface denaturation. These problems were solved by the large-scale production of genetically engineered IFNα-2 b (Intron A) in *E. coli* [3, pp. 1 – 12], [10].

5.1. Primary Structure

The amino acid sequence of IFNα-2 deduced from the DNA sequence of the cloned gene is depicted in Figure 1. This sequence has been confirmed by *N*-terminal sequencing through automated Edman degradation of the native protein and of fragments produced by either proteolytic or cyanogen bromide cleavage. The DNA sequences of 16 other IFN genes indicate an amino acid sequence homology of 75 % or more and an identity of amino acids at approximately 60 % of all positions for the majority of IFNα subtypes. However, some IFNα subtypes differ by only one amino acid and yet are produced by distinct, nonallelic genes, e.g., IFNα-A and IFNα-2. The IFNα subtypes generally consist of 165 or 166 amino acid residues preceded by a 23-amino acid signal sequence. These signal sequences are not found in the mature protein because they are removed by proteolysis during secretion of IFN by the cell.

All IFNα subtypes contain four cysteine residues. As shown in Figure 1, for IFNα-2 b these residues occur at positions 1, 29, 98, and 138. Chromatographic analysis of proteolytic fragments has shown that these amino acids form two disulfide bonds between residues 1 and 98, and residues 29 and 138. Pairing of the cysteine residues is probably the same in all IFNα subtypes. Studies with reducing agents indicate that the 29 – 138 disulfide bond is required for the full expression of biological activity, whereas the 1 – 98 disulfide bond may be disrupted without a significant loss in activity.

Based on examination of the biological activity of various recombinant hybrid IFNα molecules, IFNα appears to contain at least two distinct binding sites located at the amino and the carboxyl terminals, respectively. Each binding site is thought to interact with the IFN receptor, and the nature of the biological response is determined by the quality of fit between ligand and receptor [66]. However, other studies suggest that the final 13 carboxyl-terminal amino acids of IFNα are not required for biological activity.

Two forms of IFNβ have been cloned, and the amino acid sequence predicted from the complementary DNA sequence [67], [68]. The principal form of IFNβ produced by fibroblasts, IFNβ-1, contains 166 amino acids and exhibits approximately 30 % homology in amino acid sequence with IFNα-1. However, the region of highest homology between IFNβ-1 and IFNα-1 lies between residues 115 and 151, which suggests an important functional role for this region.

A single form of IFNγ has been identified [69]. The gene structure predicts that this protein contains 146 amino acids, significantly fewer than IFNα or IFNβ. Virtually no homology exists at the amino acid level with either IFNα or IFNβ. Another form of IFNγ that lacks three amino acids (cysteine – tyrosine – cysteine) at the amino terminus has also been cloned. The specific antiviral activity of this species appears to be higher than that of the 146-amino acid form.

5.2. Secondary and Tertiary Structure

The secondary structure of purified recombinant IFNα-2 b has been examined by circular dichroism (CD) in both the near and the far UV range (Fig. 2).

Intense, negative bands at 218 and 208 nm are characteristic of an alpha helix. Calculations based on the amplitude of these bands indicate an alpha helicity of ca. 50 %. Although the CD spectra do not indicate the presence of beta sheets, a small percentage (e.g., 0 – 10 %) may be present but undetectable in the spectrum. Near-ultraviolet CD spectra indicate two intense negative bands at 291 and 286 nm, which can be assigned to transitions of tryptophan. The intensity and location of these bands suggest that at least one of the two tryptophan residues is present in a hydrophobic environment. Weak, negative CD bands at 255, 262, and 268 nm can be assigned to phenylalanine. Titration of IFNα-2 b solution to pH 2 results in virtually complete loss of tryptophan CD bands as well as substantial depression in the CD bands representative of the alpha helix. However, the apparent loss in native conformation that occurs on acidification is completely reversible on retitration to pH 7.4. In parallel with these findings, the antiviral activity of IFNα-2 is also retained completely after exposure to pH 2 and neutralization.

Precise information on the tertiary structure of IFNα is not yet available. However, crystallization of recombinant IFNα-2 b (Fig. 3) has provided a basis for X-ray diffraction analysis

of three-dimensional structure. Needle-shaped crystals, with dimensions of ca. 0.1×0.01 mm^2, are prepared by incubation of a purified IFNα-2 solution at pH 6.0, which is near the isoelectric point of the protein [10]. Crystal dimensions vary depending on the conditions of crystallization.

Figure 3. Human IFNα-2 b (Intron A) crystals

Crystallization of a form of human IFNγ (IFNγ-D$'$), in which the five amino acids at the carboxyl terminus are deleted, has also been reported [70].

Crystals suitable for high-resolution X-ray diffraction have been prepared by vapor-diffusion equilibration against a solution of 30 % saturated ammonium sulfate in 50 mmol/L sodium acetate, pH 5.9 [70]. Rhombohedral crystals ($0.45 \times 0.45 \times 0.40$ mm) are formed after 5-d incubation at room temperature (Fig. 4). The X-ray precession photographs indicate that the crystals are trigonal. The crystals are moderately stable to X radiation and diffracted to a resolution of 0.33 nm on a rotating anode generator. The three dominant faces of the rhombohedral crystal correspond to the (110), (101), and (011) planes of the rhombohedral unit cell. The measured density of the crystals is 1.224 g/cm^3 in a Ficoll – 45 % ammonium sulfate solution. The calculated mass of the protein per unit volume is 63 200, which indicates that four molecules of IFNγ-D$'$ are present in the asymmetric unit. Diffraction data from native crystals and from several heavy-atom derivatives have been collected by oscillation photography with synchrotron radiation [70]. The intensity data sets from native crystals (resolution to 0.285 nm) are being analyzed to determine the

three-dimensional structure at this degree of resolution.

5.3. Solution Properties

Based on their predicted amino acid compositions, the polypeptide molecular masses for human IFNα, β, γ are 19 269, 19 990, and 17 145, respectively. However, under certain conditions the apparent molecular mass of IFNα in solution appears to be considerably higher than the polypeptide molecular mass [10]. Sedimentation velocity experiments have established that IFNα-2 undergoes self-association to yield a molecular mass at least three times that of the monomer. Lowering the pH from 7 to 2 favors monomer formation. Under the low protein concentration in a biological assay, it is anticipated that IFNα is completely monomeric; thus, the monomer is probably the active species. Even under highly concentrated conditions (e.g., 10 mg/mL or higher), IFNα-2 b appears to be very soluble. At its isoelectric point (ca. pH 6.0), IFNα is relatively insoluble and can be crystallized readily. In contrast, IFNγ appears to form a stable dimer that does not dissociate on dilution and has a highly basic isoelectric point of ca. 9.5.

6. Purification

6.1. Natural Leukocyte IFN

Starting materials used for the purification of human IFN include leukocytes isolated from whole blood, neonatal fibroblasts, and lymphoblastoid and various leukemic cell lines. The principal source for purification of IFN prior to the use of genetically engineered microorganisms was human cell cultures treated with an appropriate inducer (e.g., a virus or a double-stranded polynucleotide). The principal problem with the isolation of IFN from such sources is the low level of expression of IFN due to its potent biological activity. Large starting volumes and multiple purification steps are thus required, and only small quantities of material can be purified. For example, in 1978, two laboratories in Helsinki together produced only 1.3 g of IFNα of <1 % purity from 90 000 bags (45 000 L) of donated blood. Lack of precision in the antiviral assay commonly employed for monitoring the degree of purification (see Section 7.1) has also been a problem in the development of purification protocols.

Partially purified human leukocyte IFN was first developed by CANTELL and his associates in Finland and has been available in limited quantities for clinical trials since 1973 [71]. In this procedure, fresh blood from normal donors is centrifuged, and the leukocyte fraction (i.e., the buffy coat) is removed. Pooled leukocytes are treated with 0.83 % ammonium chloride to lyse residual erythrocyte contaminants, suspended in a culture medium (e.g., Eagle's minimum essential medium), and then primed with high-titer crude IFN. Interferons production (primarily by monocytes) is then induced by addition of Sendai virus. After overnight incubation, the cells and debris are removed by centrifugation; the supernatant containing crude IFN is the starting material for purification.

Crude IFN is first precipitated with potassium thiocyanate at pH 3.4 and extracted with 95 % ethanol. Extraction with acidified ethanol inactivates residual Sendai virus and partially purifies the IFN because not all proteins redissolve. The pH is then increased stepwise to precipitate contaminating proteins, which are removed by centrifugation. The IFN is precipitated at pH 8, concentrated, and dialyzed against phosphate-buffered saline.

The specific antiviral activity of the IFN preparation is approximately 10^6 IU/mg of protein, which represents approximately 1 % purity. The net yield per unit of blood (i.e., 0.5 L) is ca. $(5-7)\times10^6$ antiviral units. The final product contains a number of different species of IFNα,

including α-1, α-2, and α-4. Other lymphokines (i.e., hormones released by leukocytes such as interleukin-1 and 2) probably also contaminate the preparation.

The partially purified leukocyte IFN preparation can be purified further to a specific activity of ca. 10^8 IU/mg of protein by chromatography on an immobilized monoclonal antibody referred to as NK-2. The IFN is eluted from the column by exposure to low pH. However, the relative composition of IFNα subtypes in this preparation differs from that in crude IFN prior to chromatography because the NK-2 antibody does not bind all IFNα species equally.

6.2. Recombinant IFNα (→Genetic Engineering, Chap. 5.1.)

Purification of recombinant IFN from a genetically engineered microorganism poses unique problems distinct from those encountered in purification from natural sources [72]. The following requirements must be satisfied:

1) A procedure for efficient extraction of IFN from the cell that does not denature the protein must be developed. High concentrations of a conformation-disrupting agent such as urea or guanidine should be avoided for extraction because renaturation of the extracted protein may be difficult or impossible. This consideration is especially important for human IFNα because two disulfide bonds must be reformed in the native structure and the use of a chaotrope may lead to incorrect disulfide pairing. Furthermore, even if the final product is biologically active and appears to be properly refolded, small quantities of incorrectly folded material may be highly antigenic and remain undetected by standard analytical methods.
2) The extraction and purification procedure must yield a protein that is uncontaminated with bacterial pyrogens (gram-negative bacterial lipopolysaccharides that increase body temperature when injected parenterally). Pyrogens are not readily removed from purified IFN preparations because effective methods for their removal from solution (e.g., adsorption on activated charcoal or destruction with ionizing radiation) may damage the biological activity or structure of the recombinant protein.
3) The purified IFN must be substantially free of nucleic acids and proteins derived from the host microorganism if it is to be employed in human clinical trials.
4) The product must be a homogeneous IFN species that is free of aggregates and proteolytic fragments. These IFN-related components are of special concern because they could render the product antigenic when injected into humans.
5) To be commercially viable, purification must be achieved with a good yield (e.g., 20 %) of biological activity (e.g., antiviral units).

Purification of recombinant IFNα from *E. coli* for the IFNδ-4 α-2/α-1 hybrid that was genetically engineered to contain amino acid residues 4 – 62 of IFNα-2 and 54 – 166 of IFNα-1 is summarized in Table 3. The vector for this species was a PBR-322-based plasmid under control of the *lac* promoter [73] (see also →Genetic Engineering, Chap. 4.1.1.). The purification of IFN is monitored by following changes in specific antiviral activity (IU) expressed per milligram of protein.

The *E. coli* extract is prepared by acidification of the bacteria to pH 2, followed by adjustment to neutral pH (see Section 6.1) [74]. This procedure exploits the acid stability of type I (α and β) IFNs (see chap. 2) and avoids high concentrations of denaturants. The first purification step removes nucleic acids and contaminating *E. coli* proteins by acidification to pH 4.5 followed by centrifugation and is accompanied by a 20-fold increase in specific antiviral activity. The stability of IFNα at low pH and in organic solvents permits subsequent precipitation by addition of trichloroacetic acid and extraction from the precipitate with ethanol. This step increases the specific activity by an additional 20-fold and also concentrates the IFN solution with virtually no loss in activity. The 118 % yield indicates complete recovery of antiviral activity within the experimental accuracy of the assay. The next step consists of affinity chromatography on a blue dextran affinity medium [Matrex Gel Blue A (Cibracron Blue F 3 GA) Sepharose]. This resin is used because both human and murine IFNs bind to blue dextran. Elution from this column is achieved with

sodium chloride solution (2 mol/L). The final purification step can be performed in two ways: (1) repeated cycles of selective precipitation by dialyzing to low ionic strength and redissolving in 2 mol/L sodium chloride or (2) selective precipitation followed by ion-exchange chromatography on diethylaminoethyl (DEAE) Sepharose. The specific activity of the final product prepared by either procedure is 7×10^7 IU/mg, which represents a 140-fold purification.

An alternative approach for purifying recombinant IFNα employs immunosorbent chromatography with an immobilized monoclonal antibody [72]. Purification of IFNα-5 by this technique is summarized in Table 4.

The IFNα-5 is extracted by acidification of *E. coli* followed by neutralization (see Section 6.1). Extracted IFN is adsorbed on silica gel and eluted by lowering the pH to 2.0, which results in an almost tenfold increase in specific activity. Silica gel chromatography also removes the majority of contaminating nucleic acids in the unbound fraction. Matrex Gel Blue A chromatography results in a further 3.3-fold purification. Next, IFN is adsorbed onto an anion-exchange resin (i.e., DEAE Sepharose) and eluted with a pH gradient from 8.0 to 6.0, resulting in an additional tenfold increase in specific activity. The DEAE Sepharose eluate is purified further on an immobilized monoclonal antibody, YOK Sepharose. Elution is achieved with 0.1 mol/L sodium citrate, pH 2.0, to give a final specific activity of 1.9×10^8 IU/mg.

6.3. Removal of Pyrogens

The final IFN preparation should be low in pyrogenic substances if it is to be employed in clinical trials (see Section 6.2). Although the purification protocols described in Sections 6.1 and 6.2 generally result in a product that is very low in pyrogens (i.e., 5 – 10 ng of endotoxin per milligram of protein, determined as described in Section 7.2), preparations with high pyrogen levels are occasionally encountered. An effective procedure for lowering the endotoxin level of these preparations is recycling isolelectric focusing (RIEF). Isoelectric focusing is based on the principle that charged substances migrate in an electric field and a stable pH gradient to a pH at which their net change is zero. In the RIEF apparatus designed by Bier et al. [75], the protein solution is continuously recycled between a multichannel heat exchange reservoir and a multichannel focusing cell. Thus, heat is dissipated in the heat exchange reservoir and not in the focusing cell. As shown in Figure 5, when RIEF is applied to a solution of IFNα-2 with a high pyrogen content, the majority of endotoxins and the IFNα-2 migrate to different pH values [76]. Thus, whereas endotoxins reach maximum levels at pH 5.07 (channel 5), the antiviral activity of IFNα-2 peaks at pH 6.4 (channel 10).

In the removal of contaminating pyrogens from IFNα-2, a 40-fold purification is obtained from a single RIEF experiment, which results in a pyrogen level of 12.5 ng/mg of protein, compared to 500 ng/mg of protein prior to RIEF. No apparent loss in specific antiviral activity is observed, and the total recovery of IFN activity

Figure 5. Recycling isoelectric focusing (RIEF) of human recombinant IFNα-2 b (Intron A) containing *Escherichia coli* pyrogens (endotoxins)
The apparatus was prefocused with 0.1 % ampholines (pH range 3 – 10) in urea (4 mol/L) for 60 min followed by addition of the sample. Protein concentration was determined from the optical density reading at 280 nm; pyrogen levels were assayed by the limulus amebocyte lysate assay, and antiviral activity was determined by CPE-inhibition assay.

is >90 %. The ampholines used to establish the pH gradient are finally removed from the preparation by crystallization of the protein, gel filtration chromatography, or ammonium sulfate precipitation.

7. Quality Specifications

7.1. Purity

Purified IFN must be shown to be biologically active, and its activity must remain constant from batch to batch. Because IFN was originally defined in terms of its antiviral activity, quantitation of antiviral activity per milligram of purified protein is routinely employed for characterization of purified product. The most commonly employed assay, which is readily adapted to screening large numbers of samples, is the *cytopathic effect- (CPE-) inhibition assay*. This assay is based on the ability of IFN to interfere with the cytopathic effects (e.g., cell lysis) caused by viruses. In a simple CPE assay, IFN is serially diluted (usually by a factor of two) in the cells of a microtiter plate, and target cells (e.g., human foreskin diploid fibroblasts) are then added to each well. Cells to which IFN has not been added are also included as controls. After an incubation period (e.g., 4 h), a challenge virus (e.g., encephalomyocarditis virus) is added, followed by a further period of incubation. In the presence of IFN, cells are protected from viral infection and can be detected by staining with a dye such as Crystal Violet. However, in the absence of IFN, the cells lyse and are not stained by the dye because they do not adhere to the microtiter plate. The end point is arbitrarily defined (e.g., 50 % protection against viral infectivity). An appropriate international reference standard provided by the World Health Organization is included in each microtiter plate and allows conversion to the international antiviral units (IU) established by international accord. Further details of the CPE-inhibition assay are described in [77].

Figure 6. Polyacrylamide gel electrophoresis of purified recombinant IFNα subtypes
Before loading, 0.01 mg of each subtype was boiled for 2 min in 1 % 2-mercaptoethanol, 1 % sodium dodecyl sulfate, and 10 % glycerol dissolved in 0.06 mol/L Tris hydrochloride, pH 6.8, containing 0.001 % bromophenol blue. Discontinuous SDS – PAGE was run according to [79].
a) Standard proteins (lysozyme, β-lactoglobulin, carbonic anhydrase, ovalbumin, and bovine serum albumin); b) IFNα-1; c) IFNδ-4 α-1; d) IFNα-2; e) IFNδ-4 α-2/α-1; f) IFNα-4; g) IFNα-7

Sodium dodecyl sulfate – polyacrylamide gel electrophoresis is a powerful technique for demonstrating the purity of the final IFN preparation [78]. The quantitation of impurities and sensitivity of the method depend on the nature of the stain employed for protein detection. Quantities of protein as low as 0.05 – 0.1 µg can be detected by staining with Coomassie Blue R 250, whereas silver staining may result in detection of levels of impurities up to 100-fold lower. However, silver-stained gels must be interpreted with caution because staining intensity varies widely among proteins (up to a factor of ten). A typical gel electrophoresis of purified recombinant IFNα subtypes stained with Coomassie Blue R 250 is presented in Figure 6; SDS-PAGE reveals a purity of $\geq$95 % for each subtype, which was confirmed by silver staining. The two components observed for the δ-4 α-2/α-1 hybrid (Fig. 6, lane e) were both demonstrated to be IFN-related. Approximate quantitation of impurities can be achieved by electrophoresis at IFN loading levels ranging from 25 to 0.05 µg. The loading level at which an impurity disappears relative to the main component can be used to calculate the approximate percentage of impurity. The SDS-PAGE technique can also be employed for estimation of apparent molecular mass by comparison to the migration of standards with known molecular mass. Thus, for example, the average apparent molecular mass of IFNα-2 was observed to be 18 500 $\pm$ 600, the standard deviation representing gel-to-gel variation. The calculated molecular mass of IFNα-2 is 19 270, in good agreement with the experimental value.

Reversed-phase high-performance liquid chromatography (HPLC) is also employed to characterize the purity of the final product [80]. Reversed-phase HPLC of a clinical-grade sample of IFNα-2 b prior to formulation is presented in Figure 7. Results indicate a high degree of homogeneity, in agreement with those obtained by SDS-PAGE.

Figure 7. Reversed-phase HPLC of purified recombinant human IFNα-2 b (Intron A)
Chromatography was performed on a Water Associates μ-Bondapak C-18 column (30 cm $\times$ 3.9 mm). The eluting gradient extends from 31.4 to 62.7 % acetonitrile containing 0.01 mol/L trifluoroacetic acid at a flow rate of 1 mL/min for 30 min. Detection was accomplished by monitoring fluorescence after post-column derivatization with *o*-phthalaldehyde. The first peak is caused by the solvent.

Amino acid analysis can also be used to characterize the purified preparation. Table 5 contains the average amino acid analysis of 15 batches of purified IFNα-2 b. Interferon was first hydrolyzed with 6.7 mol/L hydrochloric acid for 18 h at 160 °C, followed by chromatographic resolution of the individual amino acids on a C-18 HPLC reversed-phase column utilizing paired ion chromatography [81]. The amino acids were detected by fluorescence following postcolumn derivatization with *o*-phthalaldehyde. Excellent agreement was observed between experimental and theoretical values.

Amino acid sequencing provides a more sensitive method than amino acid analysis for detecting contaminating proteins, as well as for demonstrating that the recombinant protein has the correct amino acid sequence predicted from

the nucleotide sequence of the gene. For example, *N*-terminal sequencing has been achieved for recombinant IFNα-2 by using automated Edman degradation in a gas-phase sequenator [82].

Table 5. Amino acid analysis of recombinant human IFNα-2 b

Amino acid	Theoretical content, mol %	Measured content, mol %
Aspartic acid, asparagine	7.74	9.06 ± 0.46
Serine	9.03	10.33 ± 0.48
Glycine	3.23	3.80 ± 0.91
Glutamic acid, glutamine	16.77	19.03 ± 0.79
Threonine	6.45	5.54 ± 0.58
Alanine	5.16	5.61 ± 0.58
Valine	4.52	2.62 ± 0.23
Methionine	3.23	2.82 ± 0.59
Tyrosine	3.23	2.81 ± 0.45
Isoleucine	5.16	3.52 ± 0.39
Leucine	13.55	13.96 ± 0.46
Phenylalanine	6.45	6.51 ± 0.20
Histidine	1.94	1.95 ± 0.15
Lysine	7.10	6.53 ± 0.58
Arginine	6.45	5.99 ± 0.70

The phenylthiohydantoin – amino acids were resolved by reversed-phase HPLC on a cyanopropyl silane column, with acetonitrile – methanol (4 : 1) as eluent. Sequencing was performed after reduction with dithiothreitol and alkylation with iodoacetamide to permit identification of cysteine residues. The first 57 amino acids agreed completely with the amino acid sequence predicted from the complementary DNA (Fig. 1). In addition, by utilizing peptide fragments produced by cyanogen bromide treatment (which cleaves the protein at methionyl residues), 90 % of the amino acid sequence was determined. Tryptic digestion of the C-terminal cyanogen bromide fragment followed by reversed-phase HPLC and amino acid analysis of the separated components was performed to identify glutamic acid as the C-terminal amino acid. The amino acid sequence was also surveyed by gas chromatography – mass spectrometry of fragments of IFNα-2 produced by subtilisin cleavage followed by trifluoroacetylation and permethylation. Selected sequences with IFNα-2 were identified and demonstrated to correspond to the gene structure.

7.2. Pyrogenicity Testing

Amebocytes circulating in the horseshoe crab (*Limulus*) hemolymph contain a coagulation system that is highly sensitive to gram-negative bacterial endotoxins [83]. The *Limulus* amebocyte lysates form a firm gel in the presence of low levels of endotoxin. The "limulus test" for detection of endotoxins, based on this gelation reaction, is extensively employed in the pharmaceutical industry. As shown in Figure 8, extremely low endotoxin levels are detectable in purified preparations of recombinant IFNα-2, in which the values generally are significantly lower than 1.0 ng/mg of protein.

Figure 8. Pyrogenicity of recombinant human IFNα-2 b (Intron A)
IFN dose, IU/kg: ■ 0.75; ● 1.5; ♦ 2.5

An alternative, traditional method for investigating pyrogen content is to measure the *increase in body temperature* following intravenous injection into rabbits. However, as shown in Figure 8, no apparent correlation existed between temperature increase and either IFN dose or endotoxin level measured in the limulus test. The in vivo test is further complicated by the fact that IFN itself has inherent pyrogenic properties. Thus, the limulus test appears to be a convenient and easily performed in vitro test for estimation of endotoxin levels.

8. Clinical Studies

Although IFN was first discovered in 1957, not until 1981 were large enough quantities of purified recombinant IFNα available to permit the initiation of phase I/II human clinical trials. To date over 2000 patients with either advanced malignancies or viral infections have been treated with IFNα-2 b (Intron A). Despite the fact that cancer patients treated with Intron A generally displayed poor prognosis as well as resistance to standard chemotherapy, a number of patients demonstrated complete recovery of long-term duration.

Phase I trials with Intron A were generally performed on patients with advanced malignancies and on a small number of normal volunteers [9], [84]. These studies indicate that Intron A is safe in humans; its toxic effects are dose-related and completely reversible. No evidence for cumulative toxicity or drug intolerance was obtained. Three routes of administration (subcutaneous, intramuscular, and intravenous) were employed in a variety of schedules. For example, Intron A was administered in an escalating daily dose for 28 d to determine the maximum tolerable dosage. Dosages were also elevated on a weekly schedule. The total daily doses examined were generally in the range of $(1-100)\times 10^6$ IU. The principal toxic effect observed in 90 % of all patients consisted of flu-like symptoms (e.g., fatigue, fever, headache). However, these dose-related effects reversed rapidly when the dosage was lowered or treatment discontinued. Other hematologic toxicities, including mild depression of white blood cell and platelet counts, and elevation of hepatic enzymes were also observed in some patients but were all reversible upon discontinuance of IFN administration. Single Intron A doses of up to 200×10^6 IU per square meter of body surface area could be tolerated when administered intravenously. However, for 5-d intravenous scheduling, 50×10^6 IU/m^2 was the maximum dose tolerated.

The pharmacokinetics of Intron A were also evaluated in phase I trials. Intravenous infusion for 30 min produced peak serum levels within 15 – 30 min. Because of a relatively short half-life, serum levels returned to base line within 4 h. However, sustained levels could be achieved by continuous intravenous infusion. Subcutaneous and intramuscular dosing demonstrated distinct pharmacokinetics with slowly rising blood levels that peaked at 4 h and maintained sustained levels for 8 – 12 h. Based on in vitro studies, the peak serum levels obtained by any of these three routes of administration should be sufficient to activate immune effector cells or to exert a direct antiproliferative effect on tumor cells.

Phase II clinical trials of Intron A have been conducted on a variety of malignancies. Results are as follows:

Active:	hairy cell leukemia
	non-Hodgkin's lymphoma
	mycosis fungoides
	Kaposi's sarcoma
	multiple myeloma
	malignant melanoma
	renal cell cancer
	bladder cancer (superficial tumors)
	ovarian cancer
Inactive:	breast cancer
	colon cancer
	non-small cell lung cancer
	prostate cancer
	acute myelogenous leukemia
To be determined:	chronic myelogenous leukemia
	chronic lymphocytic leukemia
	preleukemia
	Hodgkin's disease
	osteogenic sarcoma
	astrocytoma

Efficacy has been observed most often in hematological malignancies, particularly those of pre-B-cell and B-cell origin. For example, in hairy-cell leukemia, Intron A administered subcutaneously at relatively low doses for continuous periods produced hematological responses in ca. 90 % of patients and objective responses in ca. 75 %. Complete responses of relatively long duration have also been observed in multiple myeloma and low-grade lymphomas.

Most adult solid tumors (e.g., breast, lung, and colon) have not responded well to Intron A therapy. However, clear activity has been observed in malignant melanoma, in which the therapeutic effects were apparently schedule-dependent because continuous dosing was more efficacious than intermittent dosing. Tumor burden is probably also important in determining the response to Intron A because malignant melanoma patients with large tumor burdens appeared to have a lower incidence of response. Objective responses have also been observed in superficial bladder cancer, renal cell cancer,

ovarian cancer, and AIDS-related Kaposi's sarcoma.

Intron A has also demonstrated activity in viral indications. For example, intralesional administration into genital warts (three times weekly for three weeks) can result in complete regression of the injected warts between four and twelve weeks. Therapeutic activity has also been observed in laryngeal papillomatosis, in chronic hepatitis B, and as a prophylactive treatment for the common cold.

In all these clinical trials, the incidence of human antibody formation to Intron A was very low [85]. An antibody response was elicited in $<3\,\%$ of more than 500 patients treated systemically and in $<1\,\%$ of more than 1000 patients treated intralesionally or intranasally. Significantly higher rates of neutralizing antibody production have been reported for recombinant IFNβ (ca. 65 % of treated patients) and recombinant IFNα-2 a (Roferon) (ca. 25 – 30 % of treated patients).

The presence of neutralizing antibodies to Roferon has been reported in 7 out of 12 responding patients and in 9 out of 29 nonresponding patients with metastatic renal cell carcinoma [86]. A comparison of the medium duration of remission between antibody-positive and antibody-negative patients in this study suggested that antibody formation contributed to early relapse. Similarly, 17 out of 23 patients in a phase I clinical trial with a form of recombinant IFNβ containing a genetically engineered serine residue at position 17 showed evidence for antibody formation [87]. These data strongly support that Intron A is significantly less antigenic in human subjects than other recombinant IFNs.

1. Introduction

Iodine, I [*7553-56-2*], atomic mass 129.9044, atomic number 53, a nonmetallic element of the halogen family, appears in group 17 of the periodic table between bromine and astatine. The electronic configuration of the iodine atom is [Kr] $4d^{10}\,5s^2\,5p^5$. The relative atomic mass of the only stable isotope of iodine is 127. There are 22 artificial isotopes with masses between 117 and 139, and fourteen of these yield significant radiation, ^{122}I through ^{123}I and ^{126}I through ^{136}I (→Radionuclides). The half-lifes of the isotopes vary; the shortest, ^{136}I, has a half-life of 86 s and the longest, ^{129}I, has a half-life of 1.6×10^7 a. The isotope ^{129}I is a product of the fission of ^{235}U with slow neutrons. Because of their use in radioactive tracer work and radiotherapy, the most important radioisotopes are ^{131}I, which has a half-life of 8 d, and ^{125}I, which has a half-life of 60 d.

Iodine was first discovered by COURTOIS in 1811. While cleaning kelp pans with hot sulfuric acid, he noticed the evolution of a violet vapor that condensed as crystals on the cooler parts of the vessel. COURTOIS provided samples of this unknown material to other scientists, and in 1813 DAVY and GAY-LUSSAC identified it as a new element. GAY-LUSSAC named the substance "iode" after the Greek word for violet-colored. In 1814 GAY-LUSSAC published the results of his investigations in "Mémoire sur l'Iode".

2. Physical Properties

Iodine is the first member of the halogen family that is solid at ordinary temperature. Iodine vapor exhibits fluorescence at low pressure, emitting a yellowish-green light when illuminated by sunlight or the light from an electric arc. It also rotates the plane of polarized light when placed in a magnetic field between crossed Nicol prisms, and is thermoluminescent above 500 °C. Some physical properties of iodine are as follows:

Atomic radius	133.1 pm
Covalent radius	136 pm
Ionic radius	220 pm
Electronegativity (Pauling scale)	2.66
Electron affinity	301.9 kJ/mol

The solubilities of iodine in water and organic solvents and the color of the solutions are given in Table 1.

Table 1. Solubility of iodine in various solvents at 25 °C

Solvent	Solubility, g/kg	Color
Benzene	164.0	red
Butan-2-ol	97	brown
Carbon disulfide	197.0	red
Carbon tetrachloride	19.2	violet
Chloroform	49.7	violet
Ethanol	271.7	brown
Ether	337.3	brown
Ethyl acetate	157.0	brown
Hexane	13.2	violet
Toluene	182.5	red
Water	0.34	brown

3. Chemical Properties

The principal oxidation states of iodine are −1, +1, +3, +5, and +7, but an oxide of formula IO_2 with a formal oxidation state of +4 also exists. Except for the +4 state, thermodynamically stable compounds are formed in all these oxidation states. Iodine is the least electronegative of the halogens and is usually less violent in its reactions than fluorine, chlorine, or bromine. It exhibits mild oxidizing properties in acid solution. Iodine is a stronger oxidizing agent than astatine, the fifth halogen. A basic chemical characteristic of the halogens is the formation of a salt by direct reaction with a metal. Iodine reacts slowly with those metals that form nonvolatile iodides, for example, magnesium, especially if they are not finely divided.

Iodine forms compounds with all the elements except the noble gases, sulfur, and selenium, but only reacts indirectly with carbon, nitrogen, oxygen, and some of the noble metals. Unlike chlorine, iodine does not form compounds with carbon monoxide, nitric oxide, or sulfur dioxide. Ferric and cupric salts, and compounds of vanadium, chromium, and manganese in their highest oxidation states are reduced in acid solution by iodide ion, with the liberation of free iodine.

Reaction with Organic Compounds. Iodine reacts with hydrocarbons but the equilibria are often unfavorable because hydrogen iodide is liberated, which may reduce the alkyl iodide to the hydrocarbon with formation of iodine. Iodination can sometimes be made to go to completion by preventing the formation of free hydrogen iodide. The following three methods are commonly used:

1) Addition of an oxidizing agent, such as nitric acid, iodic acid, or a peroxide
2) Neutralization of hydrogen iodide with a base
3) Combination with mercuric salts to form mercuric iodide or an iodomercurate(II) complex [7], [8]

Iodine also adds to carbon – carbon double bonds in compounds such as ethylene, but the reactions often do not go to completion due to their reversibility.

Iodine is used as a catalyst in many organic reactions (e.g., acylation, halogenation, dehydration, isomerization, and pyrolytic decomposition).

Detection of Iodine. Iodine as the free element can be detected by the characteristic blue color given with a starch solution, or by the violet color of its vapor and of solutions in carbon tetrachloride or carbon disulfide. Iodine is also detected by the precipitation of yellow silver iodide, black palladium iodide, or yellow or red mercuric iodide. Iodine can be quantitatively determined in acidic aqueous solutions by titrating with a standard solution of sodium thiosulfate using starch as the indicator. Iodides can also be assayed by the Volhard method in which an excess of a standard silver nitrate solution is added and then backtitrated with a standard

thiocyanate solution with ferric alum as the indicator. Quantities of up to 0.05 µg of iodine can be determined by colorimetric methods.

4. Occurrence

According to the United States Geological Survey, iodine is the forty-seventh most abundant element in the earth's crust, counting the rare earths as a single element. Small quantities of iodine are widely distributed in rocks, soils, underground brines, and seawater.

Minerals. Iodine is found in nature in the following mineral forms: bruggenite, $Ca(IO_3)_2 \cdot H_2O$; dietzeite, $Ca_2(IO_3)_2 \cdot CrO_4$; iodoargyrite, AgI; iodoembolite, Ag (Cl, Br, I); lautarite [*7789-80-2*], $Ca(IO_3)_2$; and marshite [*24401-69-2*], CuI. The most important iodine-containing mineral is lautarite (anhydrous calcium iodate) [9]. Iodate occurs in the minerals bruggenite, dietzeite, and lautarite, in caliche deposits (between 2 and 50 feet below ground level) in the Atacama Desert of Chile's Antofagasta and Tarapaca Provinces. The iodate is believed to have formed from oceanic emissions during the late Tertiary and Quaternary epochs. The atmospheric photochemical oxidation of iodide to iodate is thought to have occurred in the troposphere and at ground level.

Seawater contains approximately 0.05 ppm of iodine [11]. The amount of iodine is related to the salinity. For example, the Red Sea contains 0.06 ppm and the Baltic Sea, 0.01 ppm. Iodine is concentrated by marine organisms, (e.g., sponges and seaweed) and by fish, especially in the thyroid gland and in liver oil, which contain 510 – 69 200 ppm [11]. The brown algae, *Laminaria* and *Fucus*, which grow in temperate zones of the Northern Hemisphere, have the highest iodine content (0.0279 – 0.4535 wt % after drying). The name kelp was originally applied to the ash obtained by burning seaweed, but has been extended to include the seaweed itself, particularly the varieties yielding potash, iodine, and other commercially important products.

Brines. Iodine occurs frequently as potassium or sodium iodide in subsurface brines associated with oil and gas deposits.

In Oklahoma, the United States, iodine occurs in brines with concentrations of 150 – 1200 ppm in the Morrowan formation of the Pennsylvanian age [12]. In California, brines containing 30 – 70 ppm of iodine are found in the Monterey Formation of the Middle Miocene age and in the Repetto Formation of the Pliocene age. In Michigan, brines containing about 30 ppm of iodine occur in the Sylvania Formation of the Devonian age. In playa lakes in the western United States, iodine occurs at a concentration of 14 ppm [13]. In Japan, the major iodine production occurs in the southern Kanto gas field that underlies the Chiba, Tokyo, and Kanagawa Prefectures. The primary iodine reservoirs occur in the Kiwada, Otadai, and Umegase Formations of the Pliocene to middle Pleistocene. In the Miyazaki Prefecture, iodine and natural gas are produced from the late Pliocene Sadowara and Tonogori members of the Miyazaki group. Iodine concentrations in the Sadowara gas field range between 59 and 101 ppm. Iodine is contained in the Tomigusuku Formation of the Shimajiri group of late Miocene to early Pliocene. Iodine concentrations in the southern Okinawa gas field range between 40 and 110 ppm. In the Niigata Prefecture, iodine concentrations range between 7 and 68 ppm in brines in the Niigata and Hachimori gas fields. The Niigata basin is of the Pliocene to Pleistocene age [14]. In Indonesia, iodine occurs with trace amounts of bromine in brines associated with oil. The most important iodine-producing area is the Gujangon anticline of sandstone and diatomaceous marls of the Upper Pliocene, Kailibeng Formation. The brines were reported to contain about 50 ppm of iodine [15]. Information on iodine production in other parts of the world is incomplete, but the former Soviet Union has reported iodine concentrations of 67 ppm in brines associated with oil fields at Lake Bejuk-Schor, near Baku in the Azerbaidzhan area on the Caspian Sea. Brines in the Slavyansko – Troitsko area were reported to have iodine concentrations of 80 – 120 ppm in the Neftechinski oil field near the Black Sea. At the Nebit-Dag iodine – bromine plant in Turkmenistan, iodine is produced from brines that contain 250 g/L of a combination of boron, calcium, magnesium, sodium compounds, and iodine [16].

5. Production

There have been three phases in the history of iodine production:

1) Production from seaweed began in 1817 and continued until 1959.
2) Production as a byproduct of sodium nitrate production began in 1852.
3) Production from brines began in 1854.

Six processes have been used to produce iodine from brines; the three that are currently used are described here in detail. Other, obsolete processes include the nitrate – sulfite and silver iodide methods [16].

Production from Chile Salpeter. Chile is the only location in the world where an iodine-containing deposit is commercially mined and processed. Iodine is present in the deposits as calcium iodate (lautarite and dietzeite). Processing of the deposits began prior to the 1800s. The first iodine plant opened in 1852, but closed during the first year of production. Iodine production did not begin again until about 1868 and has continued ever since. Iodine is obtained as a byproduct of sodium nitrate production.

Crushed ore is leached to give a solution containing sodium nitrate and calcium iodate. After removal of sodium nitrate by precipitation, the iodate-rich mother liquor is treated with aqueous sodium bisulfite to reduce the iodate to iodide as follows [17]:

$$2\,NaIO_3 + 6\,NaHSO_3 \rightarrow 2\,NaI + 3\,Na_2SO_4 + 3\,H_2SO_4$$

Addition of an equivalent quantity of the mother liquor then liberates free iodine.

$$5\,NaI + NaIO_3 + 3\,H_2SO_4 \rightarrow 3\,Na_2SO_4 + 3\,H_2O + 3\,I_2$$

The iodine precipitate is collected by filtration and is then fed into a melting tank where it is indirectly heated with steam to 120 °C. The molten iodine flows to a settler tank for flaking. The flaker consists of two water-cooled cylindrical drums made of Hastelloy C, an alloy which is resistant to corrosion by iodine. The molten iodine flows into the trough formed by the drums and is removed by scraping. The iodine flakes are carried by conveyor belt to be packed in fiber drums lined with double-ply polyethylene.

Production from Brine. In the United States, iodine is produced in Oklahoma by two brine processes. The brines contain ca. 300 ppm of iodine. In the *blowing-out process*, brine is pumped from the production well into a surge tank. The iodide-rich brine is fed into a column, where it is acidified with hydrochloric acid and treated with chlorine to oxidize the iodide to iodine. The iodine is stripped from the brine by steam and sent to a second column, where it is reduced and absorbed in an aqueous solution of hydriodic acid and sulfuric acid. The iodine is reduced to iodide and absorbed into solution. The iodide solution is continuously fed to a storage tank where chlorine gas precipitates crystals of elemental iodine. The iodine is filtered from the solution, and the acid stream is returned to the absorption column. The iodine is purified by melting under concentrated sulfuric acid to remove water and organic contaminants. It is then dried, and packaged in polyethylene-lined cardboard cartons for shipping [12].

The second process is an *adsorption process* that is used with brines from oil field disposal plants. The brines are skimmed in holding tanks to remove suspended oil. Oil and suspended matter are removed by filtration through sand. Hydrochloric acid is added to the brine and chlorine gas to oxidize the iodide to iodine. The brine is then passed through the absorber, where iodine is absorbed, and the waste brine is neutralized and sent to a disposal well. The adsorbent is treated with sodium hydroxide solution that elutes the iodine as sodium iodide. The iodide-rich eluate is sent to a refinery that uses a process similar to the blowing-out process.

In Japan, iodine is produced from underground brines associated with gas fields by a blowing-out process and by two adsorption processes (the ion-exchange and the sloping fluidized-bed processes) [16]. The blowing-out process is similar to that used in the United States.

In the *ion-exchange process*, the resin bed is fixed, and filtration of the brine is necessary to remove any solids before adsorption. The acidified brine is treated with chlorine to liberate iodine, which is adsorbed on an ion-exchange resin (Amberlite) as polyiodides. The iodine is released from the resin in two stages by elution with sodium hydroxide and then with sodium

chloride. After elution, the resulting iodate–iodide solution is acidified with sulfuric acid to form iodine. The iodine is then recovered from the resulting slurry by filtration or centrifugation, and purified by sublimation or by melting under sulfuric acid.

In the *sloping fluidized-bed process*, sodium iodide is also adsorbed on an ion-exchange resin, but in this case the resin is mobile and filtration of the brine is not necessary. The resin is transferred to a recovery plant, and the sodium iodide is removed as hydrogen iodide by elution with sulfuric acid. Iodine is precipitated by addition of chlorine.

The Wengfu Mine in China has reported iodine concentrations of 0.004 %. Calcining at 1050 °C yielded an iodine-rich gas that could be further processed. Iodine has been recovered during process design testing [18].

6. Quality Specifications, Transportation, and Storage

Commercial crude iodine normally has a minimum purity of 99.5 %. Impurities are chiefly water, sulfuric acid, iron, and insoluble materials. The U.S. Pharmacopoeia (U.S.P.) XVII specifies an iodine content not less than 99.8 %. The Committee on Analytical Reagents of the American Chemical Society (ACS) allows a maximum of 0.005 % total bromine and chlorine, and 0.010 % nonvolatile matter.

Crude iodine is packed in fiber drums lined with double-ply polyethylene that contain 25–50 kg. There are no specific transportation, shipping, or safety requirements. As low temperatures reduce vapor pressure and therefore decrease the rate of loss, a cool, well-ventilated storage area is recommended.

Under normal conditions, the rate of loss from intact commercial containers is negligible. Investment and maintenance costs are high for a new iodine plant using underground brines because brine sources usually do not contain high concentrations of iodine and because 1 kg of chlorine is required for the production of 1.4–1.8 kg of iodine. Electrical costs for maintaining the pumps to bring the brine to the surface, for air blowing the iodine, and for reinjecting the brine are major components of maintenance costs. Capital costs include high-quality stainless steels because iodine is highly corrosive. In addition, the brine must be leased from private landowners over large acreages for many years.

7. Uses

Iodine was first exploited commercially in 1916 in the form of potassium iodide as a remedy for goiter. In 1916, tincture of iodine and iodoform, CHI_3, were used as disinfectants for cuts and abrasions, and for sanitation. In 1939, Louis Daguerre published details of his method for making photographs on plated silver by using iodine vapor to form a thin coating of light-sensitive silver iodide crystals. Clinical uses of iodine have evolved from simple tinctures to radiopaque media, iodophors, and batteries in subcutaneously implanted pacemakers [20]. Iodine is also used in a wide variety of specialty chemicals.

Establishing an accurate end-use pattern for iodine is difficult because iodine-containing intermediates are marketed before reaching their ultimate end uses.

Uses include dietary supplements, catalysts, inks and colorants, pharmaceuticals, radiopaque diagnostic media, photographic equipment, sanitary and industrial disinfectants, and stabilizers, as well as the production of motor fuels, smog inhibitors, lubricants, high-purity metals, and iodized salt. Iodine also has applications in cloud seeding; worldwide about 11 000 kg of silver iodide is used in amounts of 10–50 g per cloud seeding.

Catalysts. The major end use of iodine is in catalysts. After the catalytic Monsanto process for producing acetic acid was introduced in the 1960s, 90 % of new acetic acid capacity used the process (→Acetic Acid, Chap. 4.2.). The process involves methanol carbonylation with an iodide-promoted rhodium complex as catalyst [20]. In the final distillation, the acetic acid often contains organic iodides; these are removed by crystallization or distillation [21]. Iodide catalysts, such as titanium tetraiodide [*7720-83-4*] and aluminum iodide [*7784-23-8*], are also significant in the dehydrogenation of butane and butene to butadiene [22], and in the preparation of stereoregular polymers [23].

Stabilizers. Consumption of iodine as a stabilizer in the manufacture of nylon for tire cord and carpets, and for converting rosins, tall oil, and other wood products to more stable forms is the second major end use [24].

Butadiene reacts with iodine and copper cyanide to yield a copper(I) iodide complex of dehydroadiponitrile. Reaction with hydrocyanic acid gives a high yield of adiponitrile, which can be catalytically hydrogenated to give hexamethylenediamine, a precursor of nylon 66 [26]. In the reaction with HCN the starting materials, copper(I) cyanide and iodine, are regenerated.

Animal Feeds. The third area of major iodine consumption is in the form of additives for animal feeds. In 1986, the recommended amount of ethylene diamine dihydroiodide [*5700-49-2*] (EDDI) consumed in animal feeds was lowered from 50 to 10 mg per head per day, in accordance with the U.S. Food and Drug Administration Compliance Policy Guideline (7125.18). Cattle and sheep are fed iodine compounds for the prevention of soft tissue lumpy jaw. The use of iodized salt has significantly reduced the incident of goiter in livestock in certain iodine-deficient geographical regions. In addition, iodized protein in fowl and cattle feed increases yields of eggs and milk. About 25 % of the reported domestic consumption of iodine was in animal feeds, primarily as the compound EDDI, but also as potassium iodide, calcium iodate [*7789-80-2*], and calcium periodate [*7790-28-5*]. Iodine is one of 14 mineral commodities listed by the National Feed Ingredients Association as being used for domestic meat production.

Disinfectant. Iodine is an effective germicide for a wide range of microorganisms. The use of iodine in sanitary preparations, such as disinfectants, is the fourth major area of consumption. Iodine is often used in conjunction with iodine-complexing nonionic surfactants or polymers (iodophors) in disinfectants that are used in dairies, laboratories, and food processing plants, and for the sanitation of dishes in restaurants [26]. Polyvinyl pyrrolidinone – iodine complex [*25655-41-8*], PVP-iodine, is extensively used because of its germicidal, bactericidal, fungicidal, and general disinfecting properties [27] (→Disinfectants). The solution contains about 10 % available iodine and about 5 % inactive iodide [28]. Globaline tablets are used by the army to disinfect water supplies without boiling [29]. Iodine is used as a disinfectant in swimming pools and is an efficient microbiocide. It is more effective than chlorine against the standard fecal indicators. High iodine concentrations are easily maintained and are more stable than chlorine [30]. A study in Florida showed that concentrations up to 5 ppm of iodine in potable water are not deleterious to health and that 1 ppm is sufficient to safely disinfect a water supply with no loss of effectiveness at high pH values [31].

Pharmaceuticals. The fifth major area of iodine consumption is in pharmaceuticals, primarily as radiopaque media, which are injected intravenously or intracerebrally to produce X-ray photographs of the internal structure of the body (→Radiopaque Media). Clinical use includes cardioangiography, cerebral angiography, arteriography, urography, and phlebography. Media listed by the U.S. International Trade Commission include meglumine diatrizoate [*131-49-7*], sodium diatrizoate [*737-31-5*], iopanoic acid [*96-83-3*], iothalamic acid [*2276-90-6*], and sodium tyropanoate [*7246-21-1*]. These substances contain between 47 and 67 wt % iodine. A nonionic contrast medium, *N,N′*-bis-(2,3-dihydroxypropyl-5-[*N*-(2,3-dihydroxypropyl)acetamidol]-2,4,6-triiodoisophthalamide, which contains 46 wt % iodine, has also been marketed [32] . Potassium iodide is widely used as an expectorant in cough medicines. Hydriodic acid and potassium iodide are used in the synthesis of amphetamine, methamphetamine, and ethylamphetamine.

Miscellaneous Uses. One of the oldest industrial uses of iodine is in photography. Up to 7 % of the silver salt in negative emulsions is iodide. Ammonium iodide [*12027-06-4*] is used as a photographic developer. Iodine is also a constituent of some dyes including 4′,5′-diiodofluorescein [*38577-97-8*], rose bengal [*11121-48-5*], and erythrosine [*16423-68-0*].

Erythrosine, certified food color Red No. 3, contains 58 % iodine and is used in carbonated soft drinks, powdered drinks, gelatin desserts, icings, and pet food. 4′,5′-Diiodofluorescein [*38577-97-8*], C.I. Solvent Red 73, is used in dyeing and printing cotton, in printing

half-silk, and in dyeing jute and straw products. Sodium iodate can also be used in the dyeing process as an oxidizing agent. Fluoroiodocarbons, such as $CF_3(CF_2)_7I$ [*507-63-1*] and $CF_3(CF_2)_7CH_2CH_2I$ [*2043-53-0*], are intermediates in the manufacture of oil and water repellents, surfactants, and fire-extinguishing foams [33], [34].

The addition of iodine to aromatic hydrocarbons, such as *n*-butylbenzene [*104-51-8*], results in the formation of charge-transfer complexes that are effective lubricants for some metals, e.g., titanium or steels [35]. Iodine is also used to produce high-purity forms of titanium, silicon, hafnium, and zirconium in the van Arkel process, which involves the formation of volatile iodides [36].

8. Economic Aspects

From 1982 to 1986, world iodine production remained fairly static and amounted to ca. 12 500 t/a (Table 2). In 1986, Japan accounted for 57 % of world production, followed by Chile (23 %), the Soviet Union (15 %), and China (3.5 %); production figures for the United States were withheld.

Table 2. Production of crude iodine [a]

Country	Production, t/a			
	1994[a]	1996[b]	2000[b]	2001[b]
Chile	5 600	5 000	9 800	10 500
China		500	500	500
Indonesia		80	70	70
Japan	7 200	6 200	6 760	6 100
Former Soviet Union		760	570	570
Total	16 700	13 800	19 100	19 600

[a] [44]
[b] [45]

In Japan, iodine is produced entirely as a by-product of natural gas production. When gas and oil prices are low, the import of world supplies of petrochemicals becomes economically viable for Japan and therefore leads to a decrease in production of domestic natural gas and the associated iodine.

Chile has large reserves of iodine associated with sodium nitrate deposits, but until 1986 had not provided capital for expansion or process improvements. In 1987, Chile completed construction of a 150-t/a iodine plant to extract iodine from waste tailings from sodium nitrate production. These tailings still contain ca. 50 % of the original iodine content. This new plant will guarantee Chile a secure source of iodine from the accumulated waste tailings.

In the United States, iodine is produced by IoChem, North American Brine Resources, and Woodward Iodine.

The United States has been dependent upon imported iodine for roughly half of domestic consumption since ca. 1960. United States imports of iodine and potassium iodide according to the exporting country are listed in Table 3.

Table 3. United States imports of iodine and potassium iodide

U.S. companies began importing large amounts of potassium iodide in 1984, due to increased demand (see Table 3).

Changes in the official price of iodine have in the past been initiated by Japan followed by Chile and the United States. The price of crude iodine in the United States increased from $ 10.40/kg in 1980 to $ 17.40/kg in 1988.

Table 4 summarizes the consumption of crude iodine in the United States according to product; iodine consumption according to use is given in Table 5.

Consumption of iodine in the United States has decreased for of a variety of reasons. Some companies have turned to importing intermediate products or sell products produced in other countries. For example, the majority of radiopaque media are now imported. Furthermore, use of the major animal feed additive, EDDI, has now been limited by the United States Department of Agriculture. In 1987, IoChem began production at a new plant in Oklahoma, in a joint venture with Schering (Federal Republic of Germany). A major portion of all iodine produced at the plant is exported to Schering.

9. Inorganic Iodine Compounds

Iodine forms binary compounds with hydrogen, metals, other halogen elements, and oxygen.

Iodides range from completely ionic to covalent structures; for example, potassium iodide is ionic and titanium tetraiodide is covalent. In general, the ionic iodides are the most soluble of the halides of a given element.

Commercially, iodides are the most important class of iodine compounds. In general, they are less fusible and volatile than chlorides or bromides. At higher temperature, even the more stable iodides show dissociation. Volatile covalent iodides, such as those of aluminum and titanium, form inflammable mixtures with air. Dry nitrogen triiodide, NI_3, formed by reacting iodine with excess ammonia, will explode at ordinary temperature under the slightest shock.

Potassium iodide [*7681-11-0*], KI, M_r 166.02, *mp* 686 °C, forms colorless cubic crystals, which are soluble in water, ethanol, methanol, and acetone. It is used in animal feeds, catalysts, photographic chemicals, and for sanitation. Potassium iodide is produced by reaction of potassium hydroxide with iodine. The product is purified by crystallization from water.

Sodium iodide [*7681-82-5*], NaI, M_r 149.92, *mp* 662 °C, forms colorless cubic crystals which are soluble in water, ethanol, acetone and glycerol. It is used in photography, for the production of organic chemicals, and as an expectorant in cough medicines. Sodium iodide is produced by the addition of sodium hydroxide or sodium carbonate to an acidic iodide solution. The anhydrous product is obtained from the solution by evaporation.

Ammonium iodide [*12027-06-4*], M_r 144.96, forms white tetragonal crystals which are soluble in water, alcohol, glycerol, and methanol. Upon heating, ammonium iodide sublimes with decomposition. It is used as an expectorant and in photographic chemicals. Ammonium iodide is prepared from ammonia, iodine, and hydrogen peroxide; from ammonia and hydrogen iodide; or from ammonium carbonate and hydrogen iodide. To prevent the crystals or solution from turning yellow due to formation of free iodine, up to 1 % of ammonium hypophosphite is added as a stabilizer.

Iodates have the general formula MIO_3, where M is a univalent metal or electropositive radical. Iodates can be prepared by dissolving

iodine in a caustic alkali solution and recovering the iodate by filtration. Iodine can be oxidized with concentrated nitric acid to iodic acid, followed by neutralization with an oxide or hydroxide; oxidation of an alkaline iodide solution with chlorine; or electrolytic oxidation of a neutral iodide solution containing chromate with a platinum anode and an iron cathode in a nondiaphragm cell. Iodates are precipitated when solutions of metal salts react with alkali-metal iodates.

Most iodates are white. The solid metallic iodates are stable and safe to handle in the pure state, but should be kept out of contact with organic substances and other combustible materials because such mixtures can be explosive. The salts of the alkali metals and magnesium are soluble in water.

Iodates and periodates can be determined by addition of excess alkali iodide in an acid solution followed by titration of the liberated iodine with thiosulfate. Periodates can be determined in the presence of iodates by adding potassium iodide to a solution buffered with borax and boric acid, and titrating the liberated iodine with sodium arsenite solution.

Hydrogen iodide [*10034-85-2*], HI, M_r 127.93, *mp* −50.9 °C, *bp* −35.4 °C, is a colorless gas which fumes in moist air. It is the least stable of the common hydrogen halides, and the best reducing agent. It cannot be prepared using strong acids because it is readily oxidized; therefore, it must be prepared from a weak acid and iodine, or by the hydrolysis of certain iodides.

Hydriodic acid is the colorless solution formed when hydrogen iodide gas dissolves in water, and at commercial strength, typically contains 47 % hydrogen iodide. Hydriodic acid is used in the preparation of iodides and is an important reagent in organic chemistry. Dilute hydriodic acid reacts with metals or their hydroxides, carbonates, and other salts to yield metal iodides.

Iodic acid [*7782-68-5*], HIO_3, M_r 175.93, forms colorless rhombohedral crystals, which decompose at 110 °C. It is prepared by oxidizing iodine with nitric acid. It is a strong oxidizing agent, oxidizing iodide to iodine, sulfite to sulfate, and hydrogen sulfide to sulfur. It reacts vigorously with dry carbon, phosphorus, and organic matter.

Polyiodides and polyhalides form when iodine or iodine halides combine with halide salts. Some examples are RbI_3 [*12298-69-0*], $[N(CH_3)_4I_9$ [*3345-37-7*], $[N(C_2H_5)_4IBr_2]$ [*20445-98-1*], and $KICl_4$ [*14323-44-5*]. Polyiodide and polyhalide salts usually form highly colored orthorhombic crystals; however, KIF_6 [*20916-97-6*] is white.

Iodine Halides. Seven iodine halides are known: IF, IF_3, IF_5 [*7783-66-6*], IF_7 [*16921-96-3*], I_2Cl_6 [*865-44-1*], ICl [*7790-99-0*], and IBr [*7789-33-5*]. All are readily formed by direct reaction of the two halogen elements.

10. Organic Iodine Compounds

As with inorganic iodides, organic iodides have higher specific gravities and indices of refraction than the corresponding chloro and bromo derivatives, and higher melting and boiling points. Compounds containing an iodine atom attached to a primary carbon atom are the most stable. Secondary compounds are less stable, and tertiary are the least stable of all. Aliphatic iodo compounds can be prepared by reacting alcohols with a mixture of iodine and red phosphorus. Other methods for preparing aliphatic iodo compounds include: the addition of iodine halides or iodine to olefins; the substitution reactions between an alkyl bromide or chloride and an alkali metal iodide; and the reaction of alcohols with triphenyl phosphite and methyl iodide.

Organic iodo compounds are highly reactive. The alkyl iodides are generally 50 – 100 times more reactive than the corresponding chlorides. Reactivity of unsaturated organic iodides is affected little if iodine is attached to one of the carbon atoms involved in the double bond, but reactivity is promoted if iodine is attached to the carbon atom in the α position to the double bond. Iodine in organic compounds can be determined after being converted into an inorganic form by heating the compound with one of the following: (1) fuming nitric acid in a sealed strong glass tube, the Carius method; (2) sodium peroxide

in a combustion container; or (3) a mixture of chromic and sulfuric acids, followed by addition of phosphoric acid and distillation into a solution of sodium arsenite [37].

Iodoform [*75-47-8*], triiodomethane, CHI_3, *mp* 119 °C, crystallizes from acetone as yellow hexagonal plates, which have a characteristic penetrating odor and are insoluble in water. The compound can be prepared by the reaction of iodine chloride with acetone in the presence of potassium hydroxide, or by reaction of chloroform with methyl iodide. Iodoform is used as a disinfectant.

Methylene iodide [*75-11-6*], CH_2I_2, M_r 267.85, *mp* 5 °C, *bp* 180 °C (101.3 kPa), is a colorless liquid when pure. It has a relative density of 3.325 at 20 °C and can be mixed with benzene (d_{20}^{20} 0.879) to produce liquids with different densities. These mixtures are used in the determination of the refractive indices of minerals and for the separation of minerals according to density.

Ethyl iodide [*75-03-6*], C_2H_5I, M_r 155.98, *bp* 72.3 °C, is a colorless liquid, which is completely miscible with ethanol and ether, but only partially miscible with benzene. Ethyl iodide is prepared by reaction of ethanol with iodine and red phosphorus.

Methyl iodide [*74-88-4*], CH_3I, M_r 141.95 *mp* −66.1 °C, *bp* 42.5 °C, is a colorless, transparent liquid, which turns brown upon exposure to light. Methyl iodide is prepared from methyl alcohol, iodine, and red phosphorus. Methyl iodide is used as a methylating agent.

Iodobenzene, [*591-50-4*], M_r 204.02, *mp* −30 °C, *bp* 188.7 °C, is a colorless liquid that rapidly turns yellow and has a characteristic odor. Iodobenzene is prepared by diazotization of aniline followed by treatment of the solution with an aqueous solution of potassium iodide, or by the action of nitric acid on a benzene and iodine mixture.

11. Toxicology and Occupational Health

Iodine is absorbed by the body and concentrated in the form of diiodotyrosine and triiodothyronine, which form thyroxine that is stored as thyroglobulin. Thyroxine is secreted by the thyroid, enters the circulation, and is carried to the peripheral tissues where it controls tissue metabolism primarily through regulation of enzyme activities (→ Hormones, Chap. 2.1.). Iodine is essential to higher animals and humans. A normal person requires about 75 mg of iodine per year, which is usually consumed as iodized salt that contains one part sodium or potassium iodide to 100 000 parts of sodium chloride. Iodine deficiency is a major cause of goiter. Studies on chickens link autoimmune thyroiditis directly with consumption of large amounts of iodine [38]. These results are also applicable to humans.

Iodine is safer to handle at ambient temperature than chlorine or bromine because it is a solid with a lower vapor pressure. When handling properly packaged containers, usual work clothes are sufficient. In the handling of solid, unpacked iodine, rubber gloves, a rubber apron, and safety goggles are recommended; more drastic situations may necessitate the use of a gas mask. The maximum safe concentration for short-term exposure of up to 1 h is 1.0 ppm. Exposure of the lungs and eyes can be irritating at concentrations of 0.1 ppm and should be avoided. Exposure in concentrations higher than 0.1 ppm for extended periods causes severe irritation to the eyes and the respiratory tract, and may lead to pulmonary edema [39]. The mean lethal oral dose for an adult is 2 – 4 g. Prolonged contact with the skin may be harmful.

Treatment includes irrigating the eyes with water or washing the contaminated body area with a 5 % solution of sodium thiosulfate, followed by saline catharsis. Iodine and concentrated solutions, including U.S.P. tincture, are classed as poisons because of their irritating effects to the gastrointestinal tract. The gastric treatment antidote is a 5 % solution of sodium thiosulfate followed by saline catharsis. Medical attention should be provided.

In the United States, the Occupational Safety and Health Administration (OSHA) has set the maximum concentration of iodine vapor permitted in the working atmosphere as 0.1 ppm [40].

The American Conference of Government and Industrial Hygienists (ACGIH) established 0.1 ppm as the TLV (TWA) for iodine. The MAK value is also 0.1 ppm. To detect iodine at this concentration, air monitoring is necessary [41].

Empty containers may be destroyed in an incinerator or decontaminated by washing with a dilute sodium thiosulfate solution. Bulk waste should be treated by controlled chemical operations to reclaim the iodine or convert it to harmless waste.

Iodine can be mixed safely with ammonia solutions in the presence of a reactive organic substance; however, contact of gaseous ammonia or its solutions with free iodine and its halogen derivatives in any form can form explosive nitrogen triiodide [*13444-85-4*], NI_3. If this dark brown to black solid forms, it should be discarded while wet or destroyed by adding a reducing agent, such as ethanol, or more of the compound to be iodinated.

In general, iodides are acutely toxic only when ingested in large amounts. Chronic ingestion or absorption through the skin may produce iodism, which is manifested by a rash, nasal drip, or headache. In severe cases, weakness, anemia, and general depression may occur. Care should be taken in handling organic iodine compounds.

In 1979 and 1986, nuclear accidents caused the release of radioactive iodine, ^{131}I, into the atmosphere. Ingestion of potassium iodide, KI, can reduce the radiation dose to the thyroid gland by up to 90 % if administered before or shortly after exposure. A dosage of 130 mg was recommended for adults. If administered 4 h after exposure, KI can block 50 % of the uptake of ^{131}I. The United States Federal Emergency Management Agency provided guidelines to state and local agencies in the United States regarding the distribution of KI for use as a thyroidal blocking agent by the general public in the vicinity of nuclear power plants [42]. Guidance on the use of radioprotective substances was delegated to the Food and Drug Administration (FDA). The FDA recommended that KI be used by people who are likely to receive more than 10 – 20 rad to the thyroid [43].

1. Introduction

Definition and Principles. In ion exchange, ions of a given charge (either cations or anions) in a solution are adsorbed on a solid material (*the ion exchanger*) and are replaced by equivalent quantities of other ions of the same charge released by the solid.

The ion exchanger may be a salt, acid, or base in solid form that is insoluble in water but hydrated. Exchange reactions take place in the water, retained by the ion exchanger; this is generally termed *swelling water* or *gel water*. The water content of the apparently dry material may constitute more than 50 % of its total mass.

Figure 1 shows the partial structure of a cation exchanger; each positive or negative ion is surrounded by water molecules.

Ion exchange forms the basis of a large number of chemical processes which can be divided into three main categories: substitution, separation, and removal of ions.

1) *Substitution.* A valuable ion (e.g., copper) can be recovered from solution and replaced by a worthless one. Similarly, a toxic ion (e.g., cyanide) can be removed from solution and replaced by a nontoxic ion.
2) *Separation.* A solution containing a number of different ions passes through a column containing beads of an ion-exchange resin. The ions are separated and emerge in order of their increasing affinity for the resin.
3) *Removal.* By using a combination of a cation resin (in the H^+ form) and an anion resin (in

Figure 1. Structure of a cation exchanger that exchanges H^+ for Na^+ ions
Swelling water is represented in the inset.

the OH^- form), all ions are removed and replaced by water (H^+OH^-). The solution is thus demineralized.

Historical Aspects. The discovery of ion exchange dates from the middle of the nineteenth century when THOMSON [1] and WAY [2] noticed that ammonium sulfate was transformed into calcium sulfate after percolation through a tube filled with soil.

In 1905, GANS [3] softened water for the first time by passing it through a column of sodium aluminosilicate that could be regenerated with sodium chloride solution. In 1935, LIEBKNECHT [4] and SMIT [5] discovered that certain types of coal could be sulfonated to give a chemically and mechanically stable cation exchanger. In addition, ADAMS and HOLMES [6] produced the first synthetic cation and anion exchangers by polycondensation of phenol with formaldehyde and a polyamine, respectively. Demineralization then became possible. At present, aluminosilicates and phenol – formaldehyde resins are reserved for special applications and sulfonated coal has been replaced by sulfonated polystyrene.

Polystyrene Resins. The first polystyrene-based resin was invented by D'ALELIO in 1944 [7]. Two years later, MCBURNEY produced polystyrene anion-exchange resins by chloromethylation and amination of the matrix [8].

The anion exchangers known until then were weakly basic and took up only strong mineral acids. The new resins produced by the McBurney process were stronger bases and could adsorb weak acids such as carbon dioxide or silica, allowing complete demineralization of water with a purity previously obtainable only by multiple distillation in platinum. Even today, ion exchange is still the only process capable of producing the water quality needed for high-pressure boilers. Reverse osmosis and electrodialysis can demineralize solutions with 50 – 90 % efficiency. Only ion exchange can "polish" the predemineralized solution with a demineralization efficiency of 99 – 99.99 %

Macroporous Resins. Two of the problems encountered in the use of ion-exchange resins are the fouling of the resin by natural organic acids present in surface waters and the mechanical stress imposed by plants operating at high

flow rates. To cope with these, three manufacturers [9–11] invented resins with a high degree of cross-linking but containing artificial open pores in the form of channels with diameters up to 150 nm that can adsorb large molecules. Resins in which the polymer is artificially expanded by the addition of a nonpolymerizable compound that is soluble in the monomer are known as *macroporous* or *macroreticular resins* (see Section 3.1). Other naturally porous resins are known as *gel resins.*

Polyacrylic Anion Exchangers. Between 1970 and 1972, a new type of anion-exchange resin with a polyacrylic matrix appeared on the market. This possesses exceptional resistance to organic fouling and a very high mechanical stability due to the elasticity of the polymer.

Uniform Size Resins. In the 1980s and 1990s, several producers developed new manufacturing technologies aimed at producing resins with particles of almost identical size.

2. Structures of Ion-Exchange Resins

An ion exchanger consists of the polymer matrix and the functional groups that interact with the ions. This article deals only with organic ion exchangers; inorganic ion exchangers are of minor importance and are primarily layer silicates and zeolites (→ Silicates, → Zeolites).

2.1. Polymer Matrices

Polystyrene Matrix. (→ Polystyrene and Styrene Copolymers). The polymerization of styrene [*100-42-5*] (vinylbenzene) under the influence of a catalyst (usually an organic peroxide) yields linear polystyrene [*9003-53-6*]. Linear polystyrene is a clear moldable plastic which is soluble in certain solvents (e.g., styrene or toluene) and has a well-defined softening point. If a proportion of divinylbenzene is mixed with styrene, the resultant polymer becomes cross-linked and is then completely insoluble.

Cross-linked polystyrene

In the manufacture of ion-exchange resins, polymerization generally occurs in suspension. Monomer droplets are formed in water and, upon completion of the polymerization process, become hard spherical beads of the polymer.

Polyacrylic Matrix. Matrices for ion exchangers can also be obtained by polymerizing an acrylate, a methacrylate, or an acrylonitrile, any of which can be cross-linked with divinylbenzene [*105-06-6*], DVB [→ Polyacrylamides and Poly(Acrylic Acids); → Polyacrylates].

Cross-linked polymethacrylate

Other Types of matrix. Other types of matrix include

1) *Phenol–formaldehyde* resins (→ Phenolic Resins) which show interesting adsorption properties
2) *Polyalkylamine resins*, obtained from polyamines by condensation with epichlorohydrin, which gives an anion exchanger directly in a single step.

2.2. Functional Groups

2.2.1. Cation-Exchange Resins

Cation-exchange resins in current use can be separated into two classes according to their active groups:

1) Strongly acidic (sulfonic groups)
2) Weakly acidic (carboxylic groups)

Strongly Acidic Cation-Exchange Resins. Chemically inert polystyrene beads are treated with concentrated sulfuric or chlorosulfonic acid to give cross-linked polystyrene 3-sulfonic acid. This material is the most widely used cation-exchange resin and is strongly acidic .

Cross-linked polystyrene 3-sulfonic acid

Examples: Amberlite IR 120, Dowex HCR, Lewatit S 100.

Weakly Acidic Carboxylic Cation-Exchange Resins. The weakly acidic resins are almost always obtained by hydrolysis of polymethylacrylate or polyacrylonitrile to give a poly(acrylic acid) matrix.

Examples: Amberlite IRC 86, Lewatit CNP.

2.2.2. Anion-Exchange Resins

Polystyrene Materials. Cross-linked polystyrene beads are treated with chloromethyl methyl ether under anhydrous conditions, with either aluminum chloride or tin(IV) chloride as catalyst. Chloromethylated polystyrene is obtained:

In a second stage, the chlorine in the chloromethylated group can be replaced by an amine or even by ammonia. Depending on the reaction selected, the anion exchanger obtained may be strongly to weakly basic. The degree of basicity can be "made to measure" because of the large number of amines available. The anion exchangers listed below are arranged in order of decreasing basicity:

where R can be

$-CH_2N^+(CH_3)_3Cl^-$ (type 1 resin)	e.g., Amberlite IRA402
$-CH_2N^+(CH_3)_2CH_2CH_2OHCl^-$ (type 2 resin)	e.g., Amberlite IRA410
$-CH_2N(CH_3)_2$	e.g., Amberlite IRA96

Resins with quaternary ammonium groups are strongly basic. Those with benzyltrimethylammonium groups are known as type 1 and are the most strongly basic, whereas those with benzyldimethylethanolammonium groups are known as type 2 and are slightly less basic.

Type 1 resins are used when total removal of anions, even those of weak acids (including silica), is essential. Type 2 resins are also basic enough to remove all anions, but they release the anions more easily during regeneration with caustic soda; as a result, they have a high exchange capacity and a better regeneration efficiency (see Section 7.1). Unfortunately, they are chemically less stable and produce greater silica leakage than type 1 resins.

Resins whose active group is an amine are generally denoted as weakly basic, although their basicity may vary considerably. Tertiary amines are sometimes called medium-base or intermediate-base resins, whereas primary amines are very weakly basic and are rarely used.

The most widely used weakly basic resins contain tertiary amino groups and adsorb any strong acids present in the solution to be treated but do not affect neutral salts or weak acids.

Manufacturers do not always indicate the chemical structure of their exchangers in their literature. Care should therefore be taken not to assume that resins are chemically identical merely because they have similar general characteristics.

Secondary and Tertiary Cross-Linking. During chloromethylation, a side reaction may occur in which the chloromethyl group of a chloromethylated benzene ring reacts with an unconverted ring, to yield a methylene bridge. These bridges form additional cross-links in the polystyrene matrix:

The amount of this secondary cross-linking can be adjusted by varying the conditions (quantity and type of catalyst, temperature) of the chloromethylation reaction. Most strongly basic and weakly basic polystyrene resins have some degree of secondary cross-linking.

Furthermore, during the amination of weakly basic resins, another type of cross-linking may be produced. This is called tertiary cross-linking and yields strongly basic quaternary groups in addition to the weakly basic tertiary groups.

Polyacrylic Resins. Polyacrylic resins are manufactured in a manner analogous to that used for polystyrene resins. Beads are prepared from an acryclic ester copolymerized with divinylbenzene by using suspension polymerization and free-radical catalysis. The polyacrylate formed is then given active groups by reaction with a polyfunctional amine containing at least one primary amino group and one secondary or, more frequently, tertiary amino group. The primary amino group reacts with the polyester to form an amide, whereas the secondary or tertiary amino group forms the active group of the anion exchanger. This method always yields a weakly basic exchanger, which can be further treated with chloromethane or dimethyl sulfate to give a quaternary strongly basic resin:

Tertiary amine
(weakly basic, e.g.,
Amberlite IRA 67)

Quaternary amine
(strongly basic, e.g.,
Amberlite IRA 458)

In principle, a wide range of anion-exchange resins can be obtained by varying the type of ester chosen as the starting material and the polyamine used for activation. In practice, the range is limited by the availability and cost of raw materials.

2.2.3. Other Types of Ion-Exchange Resins

By using polymerization and activation methods analogous to those described above, a wide variety of functional groups can be grafted onto a given polymer. Some of these groups can be used for selective uptake of ions, principally metals (Table 1).

The thiol group forms very stable bonds with certain metals, particularly mercury. The iminodiacetic, aminophosphonic, and amidoxime groups form metal complexes whose stability depends mainly on the pH of the solution. Selective adsorption of certain metals can thus be achieved by varying the pH. These types of material are known as *chelating* or *complexing resins.*

The *N*-methylglucamino group is used to make resins specific for boric acid, which is taken up as a complex.

Table 1. Principal active groups of ion exchangers used for selective uptake of metals

Active group	Formula *	Example
Thiol	$-SH$	Imac TMR
Iminodiacetic acid	$-CH_2N(CH_2COOH)_2$	Lewatit TP 207
Aminophosphonic acid	$-CH_2NHCH_2CH_2PO_3H$	Duolite C 467
Amidoxime	$-C(=NOH)NH_2$	Duolite ES 346
N-Methylglucamine	$-CH_2N(CH_3)-(CHOH)_4CH_2OH$	Amberlite IRA 743

* The active groups are substituents (R) of polystyrene with the following formula:

2.3. Adsorbent Resins and Inert Polymers

Strictly speaking, adsorbent resins are not ion exchangers but resemble them very closely. They have a high porosity and are used for the adsorption of nonionic or weakly ionized species as a complement to ion exchange. They may have cation- or anion-exchange groups or no ion-exchange groups at all. The latter are ionically inert. In order of decreasing polarity, adsorbent resins can be classified in the following manner:

1) *Ionized adsorbents* are strongly basic exchangers used in chloride form for color removal from sugar juices or as "organic scavengers" (see Section 11.1, e.g., Amberlite IRA958).
2) *Phenolic adsorbents* contain weakly basic amine and phenolic groups or phenolic groups, only. They are used to remove color bodies (colored impurities) from solutions of organic acids and food-processing streams (e.g., Duolite A561, XAD761).
3) *Inert adsorbents* are macroporous copolymers of styrene and divinylbenzene with a very high degree of cross-linking and a large surface-to-volume ratio. These resins are used to remove organic, weakly ionized, or nonionic substances, such as phenols, chlorinated solvents, antibiotics, and complexing agents, from aqueous or organic solutions (e.g., Amberlite XAD4, Diaion HP20).

Inert polymers without measurable porosity and without active groups can be used either to separate two resin layers or to keep a resin separate from a collector system.

3. Properties

3.1. Degree of Cross-Linking and Porosity

An increase in the degree of cross-linking (i.e., the weight percentage of DVB related to the total amount of monomer prior to polymerization) produces harder, less elastic resins. Resins with higher degrees of cross-linking show more resistance to oxidizing conditions that tend to decross-link the polymer. Above 10–12 % DVB, however, the structure becomes too hard and dense. Activation (i.e., chemical transformation of the inert copolymer into an ion-exchange resin) becomes difficult because access to the interior of the bead is hindered by the high density of the matrix. In addition, osmotic stress cannot be absorbed by the elasticity of the structure, which causes the bead to shatter. Finally, the rate of exchange increases in proportion to the mobility of the ions inside the exchanger bead: if the structure is too dense, ionic motion is slowed down, thus reducing the operating capacity of the resin.

For sulfonic resins, maximum operating capacity (Section 3.2) is obtained with approximately 8 % DVB.

Cross-Linking and Affinity. The greater the ionic mobility in the resin, the poorer is the differentiation between the adsorption of ionic species with the same charge. Consequently, the degree of cross-linking in the resin must be increased when greater differences in ionic affinity are required.

In water treatment, the sulfonated polystyrene resins usually have a DVB concentration of ca. 8 %. Resins with a slightly higher degree of cross-linking (10 – 12 %) are sometimes used to increase the retention of mineral ions when water of very high purity is being produced. Resins with slightly lower levels of cross-linking (5 – 7 %) may be chosen when easier desorption and, hence, better regeneration efficiency are required, especially in water softening.

Nonuniformity in the Matrix. Cross-linking reduces the retention of water in ion-exchange resins (Section 3.6). The volume occupied by this water is a measure of the resin's porosity. Cross-linking is not uniform because the DVB – DVB reaction is more rapid than that between DVB and styrene. Polymerization begins to occur around the catalyst molecules, and polymer growth is faster at sites rich in DVB than at those rich in styrene. Material with an average of 8 % DVB may contain local microscopic regions with more than 20 % DVB, whereas other regions may have less than 4 %.

Macroporous resins are made by mixing the monomers with a compound (e.g., heptane, saturated fatty acids, $C_4 - C_{10}$ alcohols or polyalcohols, or low molecular mass linear polystyrene) which expands the resin. The substance does not itself polymerize and, thus, although it acts as a solvent for the monomers, it causes the polymer to precipitate from the liquid.

Figure 2. Arrangement of structural units in gel (A) and macroporous (B) resins

Channels are formed inside the beads, producing an artificially high porosity. Resins containing such channels are described as *macroporous*, whereas other resins with natural porosity are known as *gel resins* (Fig. 2).

Macroporous resins have a higher degree of cross-linking than gel resins to strengthen the matrix and compensate for voids left by the added solvent. The porosity and mechanical strength of the resin can be modified by varying the degree of cross-linking or the amount of solvent added. Therefore, various macroporous resins are available, with different moisture-holding capacities and internal structures.

The pore diameter is ca. 100 nm in a macroporous resin and ca. 1 nm in a gel resin. The macropores form a network of channels filled with free water, and large molecules can move freely in the resin into the center of a bead. Once inside the resin, ions generally have a much shorter distance to travel before they encounter an active group: ca. 100 nm in macroporous resins and up to 500 µm in gel resins. Exchange is thus faster in a macroporous resin.

Macroporous resins are highly resistant to physical stress and generally withstand osmotic shock very well. They are therefore used in systems where mechanical and osmotic stress would otherwise cause gel resins to deteriorate rapidly, such as those involving circulation of resin, fluidized beds, high flow rates, oxidizing conditions, concentrated solutions, and short cycles.

Finally, macroporous resins are used when reversible uptake of large molecules is necessary, without fouling the resin. The adsorbents described in Section 2.3 have a macroporosity that allows selective retention of various molecules.

3.2. Exchange Capacity

Total Capacity. The total exchange capacity of a resin, expressed in equivalents per unit weight (or per unit volume), represents the number of active sites available. In polystyrene exchangers, the maximum number of active sites corresponds to the "grafting" of one active group per benzene ring. The capacity is expressed in equivalents (eq) per kilogram of dry resin (the weight capacity C_p) or equivalents per liter of wet settled resin (the volume capacity C_V). To-

Table 2. Typical capacities of ion-exchange resins ∗

Type	Amberlite	C_p, eq/kg	C_v, eq/L
Strongly acidic gel, 8 % DVB	IR120	4.5 (Na)	2.05 (Na)
Weakly acidic gel	IRC86	11.0 (H)	4.2 (H)
Strongly basic, type 1	IRA402	3.9 (Cl)	1.3 (Cl)
Strongly basic, type 2	IRA410	3.6 (Cl)	1.3 (Cl)
Strongly basic acrylic	IRA458	4.2 (Cl)	1.3 (Cl)
Weakly basic styrene	IRA96	4.7 (free base)	1.25 (free base)
Weakly basic acrylic	IRA67	5.6 (free base)	1.6 (free base)

∗ Values depend to some extent on the analytical method used for capacity determination. Macroporous strongly acidic resins have a dry weight capacity of 4.3 – 4.5 eq/kg. Their volume capacity depends greatly on their porosity, which can be adjusted within relatively broad limits. Similarly, macroporous strong base resins have dry weight capacities close to their gel counterparts, but generally lower volume capacities.

tal capacity values for some of the most common resins are given in Table 2. Equivalent resins of other brands have similar capacity values (see Table 10).

Operating Capacity. The operating capacity is defined as the proportion of total capacity used during the exchange process. It can amount to a large or small proportion of the total capacity and depends on a number of process variables including

1) Concentration and type of ions to be absorbed
2) Rate of percolation
3) Temperature
4) Depth of resin bed
5) Type, concentration, and quantity of regenerant

In a packed column, reaction between the ions in solution and those in the resin occurs over a well-defined region of the resin bed known as the *reaction zone*. When the selectivity of a resin for a dissolved ion is high (see Chap. 5), a sharp exchange wavefront is formed which moves toward the column outlet, making maximum use of the resin. The depth of the reaction zone depends on factors such as flow rate (kinetics) and ionic concentration, but is independent of column length [12].

When selectivity is low, a diffuse wavefront develops. The depth of the reaction zone then depends on the selectivity coefficient (Section 5.2) and also on the bed depth. The longer the column, the deeper is the reaction zone and the greater is the operating capacity of the resin. Figure 3 illustrates this: the top of the column contains the completely exhausted resins (a), whereas the reaction zone (b) contains partially exhausted resin. The time at which the lowest point of this zone reaches the bottom of the column (i.e., when the adsorbed ions break through the bottom of the bed) is generally taken to be the time at which the service phase is complete. A proportion of the resin is still not exhausted at the time of breakthrough.

Figure 3. Reaction zone in a resin column during percolation
a) Exhausted resin; b) Reaction zone; c) Regenerated resin

In practice, strongly acidic and strongly basic resins are never 100 % regenerated at the beginning of a cycle. The operating capacity thus represents the difference between the available capacity at the beginning of a cycle and that remaining at the end point. The most important factor is the amount of regenerant used to convert the resin to the regenerated form required at the beginning of the service cycle (c). The calculation of capacity is described in Chapter 7.

3.3. Stability and Service Life

Because ion-exchange resins must give several years of service, their stability over long periods of time is of prime importance.

Chemical Stability of the Matrix. Industrially available resins have a degree of cross-linking high enough to make them insoluble. A new resin may release minute quantities of short-chain polymers or other soluble substances, but this effect is short-lived.

Figure 4. Suitability of resins for producing ultrapure water in mixed beds [14]
Resins were tested at ambient temperature during first chlorine exposure by using an influent with 0.30 ppm active chlorine dosed as NaOCl and 0.02 – 0.03 ppm TOC.
Resins: a) Gel cation – porous gel anion; b) Gel cation – standard gel anion; c) Macroporous cation – porous gel anion; d) Macroporous cation – standard gel anion; e) Macroporous cation – macroporous anion; f) Macroporous cation – developmental anion; g) Gel cation – developmental anion

Highly oxidizing conditions (presence of chlorine or chromic acid) can attack the matrix and destroy cross-linking. A sulfonated polystyrene cation-exchange resin with 8 % DVB cross-linking withstands 0.2 mg/kg of chlorine at ambient temperature for several years and is also completely stable at 120 °C in the absence of oxidants. However, 1 mg/kg of chlorine oxidizes the polymer at a rate dependent on temperature; this breaks down the cross-linking, releases sulfonated organic compounds and causes the resin to swell until it softens, resulting in excessive head loss (sloughage) [13]. When oxidizing agents are present, highly cross-linked resins with a greater resistance to oxidation, such as the macroporous resins, should be used.

Degradation products from a cation-exchange resin may foul anion resins [14], [15]. This is particularly critical in processes designed to produce ultrapure water (Fig. 4). Oxidants break the cross-links to produce soluble, short-chain oligomers that can be measured as the total organic carbon (TOC) in the treated water (Fig. 4 A). The oligomers bear ionized active groups and thus decrease the resistivity of the treated water (Fig. 4 B). Under normal conditions of water treatment, resins can operate continuously for many years (sometimes up to 20 years) without deterioration of their physical and chemical properties.

Figure 5. Half-life of Amberlite IRA 402 as a function of temperature
Half-life is the contact time of resin with hot solution required to reduce total capacity by 50 %.

Thermal Stability of Active Groups. [16] The sulfonic group of cation-exchange resins

is extremely stable. Anion-exchange resins, on the other hand, are temperature-sensitive. When heated, Hofmann degradation may transform quaternary ammonium groups (strongly basic) into tertiary amines (weakly basic) or even destroy the active group completely. Because this reaction occurs under alkaline conditions, anion exchangers are more stable in the form of a salt than as a base.

Strongly basic type 1 resins are the most stable; the Hofmann degradation reaction becomes significant only above 50 °C (Fig. 5). At ambient temperature, these resins can last for five to seven years or more.

Type 1 resin

Type 2 resins are more liable to undergo Hofmann degradation because the hydroxyethyl group weakens the bond:

Type 2 resin

At ambient temperature, these resins lose ca. 50 % of their strongly basic groups in five years; the same effect occurs in about one year at 50 °C. (A resin in which 50 % of the strongly basic groups have been converted into weak groups, often has an unchanged operating capacity because the weakly basic groups are fully capable of taking up mineral acids).

Mechanical Stability. Polycondensation-type resins that are manufactured in bulk and broken up into irregular grains are comparatively fragile and used only in fixed beds (Section 10.2). Polystyrene and polyacrylic resins made by suspension polymerization are perfect spheres and suffer little damage when used in continuous moving-bed ion-exchange plants. However, mechanical strength can vary considerably from one product to another, and resin beads which are seen to have many internal cracks under the microscope are more likely to break under mechanical stress than crack-free products.

Gel-type anion resins are generally weaker than cation materials and are particularly poor at withstanding compression. However, new polymerization techniques produce a more uniformly structured polystyrene matrix. As a result, gel resins with high physical stability are now available. To prevent fragile resins from breaking, it is important to keep the bed clean by frequent backwashing because the water pressure on a layer of fine debris can be as much as 60 kPa.

Acrylic resins are more elastic than polystyrene materials and can normally withstand any mechanical stress encountered in practice. Macroporous resins are often the strongest of all and are used widely for the most severe stress conditions.

The less elastic resins, i.e., those with the highest degree of cross-linking (gel resins with > 8 % DVB and macroporous resins with >15 % DVB), have the disadvantage that, when they do break, they explode into minute fragments, whereas other resins break into two or three usable pieces.

Osmotic Stability. During ion exchange, the configuration around each active group in the resin changes: the adsorbed ion generally has a different size and, more important, a different hydration layer than the displaced ion. The resin bead may therefore swell or contract appreciably during the reaction. The stresses to which the resin is subjected during these volume changes are known as osmotic forces. They are very intense and can produce local pressures of several thousand kilopascals – much greater than purely mechanical stress.

Resins for industrial use must be able to withstand hundreds of cycles of exhaustion and regeneration. The nature and, hence, the strength of osmotic shock vary according to the ionic species in solution and their concentration.

Higher mechanical and osmotic strengths are obtained with resins whose matrix is sufficiently strong to withstand physical shock (attrition) but sufficiently flexible and porous to deform without breaking under the effect of osmotic shock. Some macroporous resins combine both of these qualities.

Resistance to Drying. Repeated drying and rewetting produce stresses analogous to those due to osmotic shock and can lead to fragmentation of most gel resins. Resins must therefore be kept permanently moist.

3.4. Density

Resin density is an important property because it determines the hydrodynamic behavior in counterflow systems. Resin density normally lies in the following ranges (figures in parentheses are the most common values for standard resins):

Strongly acidic cation exchangers	1.18 – 1.38 (1.28)
Weakly acidic cation exchangers	1.13 – 1.20 (1.18)
Strongly basic anion exchangers	1.07 – 1.12 (1.10)
Weakly basic anion exchangers	1.02 – 1.10 (1.05)

By choosing suitable particle sizes, several different types of resin can be used in the same column. If necessary, they can be kept separate by an upflow of water. This is used mainly in layered beds (see Section 9.3).

Resin density can be increased artificially, for example, by attaching chlorine or bromine atoms to the matrix. This yields high-density anion exchangers, which are useful when fluidized-bed operation is required. However, such "high-density" resins are not available commercially.

3.5. Particle Size

For industrial use, particle size is a compromise between the speed of the exchange reaction (which is greater with small beads) and high flow rates (which require coarse particles to minimize the head loss).

The size of the polymer droplets formed during polymerization, and hence the size of the resin beads, is determined by the polymerization technology, the suspension medium and, the monomer concentration.

Traditional polymerizations are carried out in batches in a stirred reactor. The beads produced in this way have a range of particle sizes rather than a uniform size (Table 3). The population of a resin sample (i.e., the number of beads classified according to bead diameter) has an approximately Gaussian distribution. Because the volume of a fraction is a logarithmic function of the number of beads, the particle-size distribution is often represented by a straight line on probability graph paper (Fig. 6).

Table 3. Particle-size distribution of ion-exchange resins ∗

Sieve aperture, mm	Noncumulative total (between sieves), %	Cumulative total (passing through), %
<0.315	0.2	0.2
0.315 – 0.40	1.3	1.5
0.40 – 0.50	8.5	10.0
0.50 – 0.63	30.8	40.8
0.63 – 0.80	33.3	74.1
0.80 – 1.00	20.4	94.5
1.00 – 1.25	4.9	99.4
>1.25	0.6	100.0

∗ Effective particle size 0.50 mm, mean diameter 0.68 mm, uniformity coefficient 0.73/0.50 = 1.46

Figure 6. Typical particle-size distribution in a normal resin

For Gaussian distribution, the particle-size distribution is defined by

1) The *mean diameter* (corresponding to the mesh size of a sieve allowing 50 % of the beads to pass)
2) The *uniformity coefficient*, U.C. (given by the ratio between the aperture of a sieve allowing 60 % of the beads to pass and that of a sieve allowing 10 % to pass. The latter theoretical sieve is known as the *effective size.*

$$\text{U.C.} = x_{60\,\%}/x_{10\,\%}$$

The closer the uniformity coefficient is to unity, the narrower is the Gaussian curve and hence the smaller is the range of particle size. Resins produced with the traditional stirred-reactor process usually have a uniformity coefficient of 1.5 to 1.9.

Several producers now offer ion-exchange resins with a very uniform particle size distribution, which are produced with different polymerization technologies. In one technique, the monomers are injected into the suspension medium through a plate perforated with thousands of very small holes. Droplets of the monomer mixture with an almost identical volume are expelled. The uniformity coefficient of resins produced in this way is always less than 1.2, often in the range of 1.05 – 1.10. Examples of such resins are Amberjet (Rohm and Haas), Dowex Monosphere (Dow Chemical), and Lewatit Monoplus (Bayer).

3.6. Moisture Content

Ion-exchange resins carry both fixed and mobile ions which are always surrounded by water molecules located in the interior of the resin beads. The water retention capacity governs the kinetics, exchange capacity, and mechanical strength of ion-exchange resins.

The moisture content or *moisture-holding capacity* (MHC) is defined as

$$\text{MHC} = \left(P_{\text{Hydr}} - P_{\text{Dry}}\right)/P_{\text{Hydr}}$$

where P_{Hydr} is the weight of the hydrated resin sample and P_{Dry} the weight of the same sample after drying.

The MHC of an ion-exchange resin is an inverse function of the degree of cross-linking unless the porosity or degree of cross-linking in the polymer is artificially increased (as in macroporous resins). Figure 7 shows how the moisture content varies with the proportion of DVB for gel-type sulfonic polystyrene resins.

Figure 7. Variation of moisture content (A) and total capacity (B) with the degree of cross-linking in a sulfonated polystyrene resin in sodium form

Another useful quantity is the *dry matter* (DM) defined as

$$\text{DM} = P_{\text{Dry}}/V_{\text{Hydr}}$$

where P_{Dry} is the weight of the dry resin sample and V_{Hydr} the volume of the sample before drying. Although they are closely connected, no simple arithmetical relationship exists between dry matter and moisture content. In all cases, the ionic form of the resin at the time of measurement should be quoted.

4. Ion-Exchange Reactions

4.1. Cation Exchange

General cation exchange is used widely to remove undesirable ions from a solution without changing the total ionic concentration or pH. The resin can be used in many ionic forms, but the sodium form is usually preferred because the resin has a relatively low affinity for sodium, which facilitates the adsorption of other metals. Furthermore, sodium chloride is an inexpensive regenerant.

The following reaction is used to treat wine (R denotes the resin):

$$R^-Na^+ + K^+\,(HTartrate)^- \longrightarrow R^-K^+ + Na^+\,(HTartrate)^-$$

The reaction used in water softening is

$$2\,R^-Na^+ + Ca^{2+}(HCO_3^-)_2 \longrightarrow (R^-)_2Ca^{2+} + 2\,Na^+HCO_3^-$$

In each case, the resin is regenerated by reversal of the reaction with sodium chloride solution.

Hydrogen Exchange in Strongly Acidic Resins. The replacement of metal ions with hydrogen ions leads to a reduction of the total dissolved solids in solution and the production of free acid:

$$R^-H^+ + Na^+Cl^- \longrightarrow R^-Na^+ + H^+Cl^-$$

This reaction is used as the first stage in the demineralization of water and other solutions. It is sometimes called salt splitting. Regeneration is carried out with a mineral acid.

Hydrogen Exchange in Weakly Acidic Resins. Carboxylic resins are such weak acids that they ionize only slightly under acid conditions. However, they have such a high affinity for divalent metals that in the presence of these metals, they are forced to ionize and therefore remain active under slightly acidic conditions down to ca. pH 4.5.

$$2\,RCOOH + Mg(OH)_2 \longrightarrow (RCOO)_2Mg + 2\,H_2O$$

$$2\,RCOOH + Na_2CO_3 \longrightarrow 2\,RCOONa + H_2O + CO_2$$

$$RCOOH + NaCl \text{ No reaction}$$

$$2\,RCOOH + CaCl_2 \longleftarrow (RCOO)_2Ca + 2\,HCl$$

However, H^+ from carboxylic resins cannot remove significant amounts of metals from solutions of mineral acid salts because the acid produced quickly lowers the pH and prevents further ion exchange. In this case, ion exchange is controlled by the basicity of the anion in solution. A strongly nucleophilic anion "tears off" hydrogen from the carboxylic group, which takes up the associated cation in exchange, whereas a stable anion does not react significantly.

Because the resin has a very high affinity for divalent ions (the effect of chelation), but only moderate affinity for monovalent ions, it has a high capacity for removing calcium and magnesium from bicarbonate solution but takes up only a small amount of sodium. This occurs because sufficient carbonic acid is formed to suppress the exchange of monovalent ions:

$$RCOOH + NaHCO_3 \longleftarrow RCOONa + H_2O + CO_2$$

$$2RCOOH + Ca(HCO_3)_2 \longrightarrow (RCOO)_2Ca + 2H_2O + 2CO_2$$

Carboxylic exchangers (weakly acidic) are selective: they preferentially remove divalent or trivalent cations until competition arises from alkaline anions present in solution.

Selective Exchange in Weakly Acidic and Complexing Resins. Because carboxylic resins take up multivalent cations in preference to monovalent ones and are regenerated very easily, they can be used for selective removal of divalent and trivalent metals, even when high concentrations of alkaline cations are present. To achieve this, the exchanger is first converted to the monovalent sodium form:

$$RCOOH + NaOH \longrightarrow RCOONa + H_2O$$

which allows exchange of neutral salts:

$$2\,RCOONa + ZnSO_4 \longrightarrow (RCOO)_2Zn + Na_2SO_4$$

At the end of the cycle, the resin is regenerated with acid:

$$(RCOO)_2Zn + H_2SO_4 \longrightarrow 2\,RCOOH + ZnSO_4$$

and is reconverted to the monovalent sodium form by reaction with sodium hydroxide.

4.2. Anion Exchange

General Anion Exchange. The most widely used resin for general anion exchange is a strongly basic exchanger in chloride form:

$$R^+Cl^- + Na^+NO_3^- \longrightarrow R^+NO_3^- + Na^+Cl^-$$

This process is used to remove natural organic acids (e.g., humic acid, see Section 7.3) and nitrate from water and in hydrometallurgy to selectively adsorb metals that form anionic complexes:

$$n\,R^+Cl^- + (Na^+)_n\ \mathrm{Humate}^{n-} \longrightarrow (R^+)_n\ \mathrm{Humate}^{n-} + n\,Na^+Cl^-$$

$$R^+Cl^- + Na^+[Au(CN)_2]^- \longrightarrow R^+[Au(CN_2]^- + Na^+Cl^-$$

The resins are regenerated by reversal of the reactions with sodium chloride solution.

Acid Absorption in Strongly Basic Resins is the most widely used form of anion exchange. When it follows hydrogen exchange in strongly acidic resins (Section 4.1), it completes the demineralizing process:

$$R^+OH^- + H^+Cl^- \longrightarrow R^+Cl^- + H_2O$$

$$R^+OH^- + CO_2 \longrightarrow R^+HCO_3^-$$

Regeneration of the bicarbonate form of the resin requires two equivalents of OH^- ions per equivalent of HCO_3^- taken up, because half the OH^- neutralizes the bicarbonate and converts it to carbonate. The same applies to silica.

Acid Absorption in Weakly Basic Resins. Weakly basic resins, in which the active groups are usually amines, do not have a true hydroxide form. They ionize only under acidic conditions:

$$RN(CH_3)_2 + H^+Cl^- \longrightarrow RN^+H(CH_3)_2Cl^-$$

Under alkaline conditions, they exist as free bases and can therefore adsorb acids in the same way that free ammonia reacts with hydrochloric acid to form ammonium chloride. In practice, they are called the "chloride form". Weakly basic resins can only adsorb strong acids. Neutral salts are not "split":

$$RN(CH_3)_2 + NaCl \text{ No reaction}$$

This is because no H^+ ion exists to which the nucleophilic base can give its electrons and thus balance the anion. Similarly, weak acids do not have dissociated H^+ ions, so they are taken up only in very small amounts, if at all:

$$RN(CH_3)_2 + CO_2 + H_2O \rightleftharpoons RN^+H(CH_3)_2 + HCO_3^-$$

$$RN(CH_3)_2 + SiO_2 \text{ No reaction}$$

Weakly basic exchangers can be regenerated with ammonia or sodium carbonate:

$$RN(CH_3)_2 \cdot HCl + NH_3 \longrightarrow RN(CH_3)_2 + NH_4Cl$$

$$RN(CH_3)_2 \cdot HCl + Na_2CO_3 \longrightarrow RN(CH_3)_2 + NaCl + NaHCO_3$$

4.3. Cation and Anion Exchange in Water Treatment

Figure 8 summarizes the way in which the various forms of ion exchange described in Sections 4.1 and 4.2 are used in water treatment. The composition of raw water is described in detail in Section 7.3.

5. Ion-Exchange Equilibria

5.1. Dissociation and pK Value

Dissociation of the acid group in a cation-exchange resin is described by the equilibrium reaction

$$R \cdot H \rightleftharpoons R^- + H^+$$

where R^- is the co-ion fixed in the matrix structure. The acidity of the resin is defined by its degree of dissociation at equilibrium

$$K = [\underline{R}^-] \cdot [\underline{H}^+] \,/\, [\underline{RH}]$$

where K is the equilibrium constant; the quantities in square brackets represent concentrations, and underlines indicate the resin phase rather than the aqueous phase. The pK is defined as

$$pK = -\log K$$

Figure 8. Summary of the kinds of ion exchange used in water treatment
SAC = strongly acidic cation exchangers; SBA = strongly basic anion exchangers; WAC = weakly acidic cation exchangers; WBA = weakly basic anion exchangers

Cation-exchange resins can be titrated (Fig. 9) with sodium hydroxide in the presence of sodium chloride. Uptake of Na^+ by the cation-exchange resin in H^+ form occurs:

$$R^-H^+ + Na^+ \longrightarrow R^-Na^+ + H^+ \quad (1)$$

The H^+ ions released by the resin combine immediately with the OH^- ions from the alkali

$$H^+ + OH^- \longrightarrow H_2O$$

and drive the reaction shown in Equation (1) to completion.

At the beginning of titration, the strongly acidic (sulfonic) resin Amberlite IR 120 exchanges sodium ions from sodium chloride, and released H^+ ions lower the pH of the aqueous phase (Fig. 9, curve a). The pH remains low as long as the resin releases H^+ ions to replace the H^+ ions picked up from the added sodium hydroxide solution. As soon as all H^+ ions have

been replaced in the resin, further addition of sodium hydroxide raises the pH sharply.

Figure 9. Titration curves of cation-exchange resins
a) Amberlite IR 120, sulfonic acid resin; b) Amberlite IRC 86 carboxylic acid resin

The weakly acidic (carboxylic) resin Amberlite IRC 86 behaves differently. Because its acidic groups are weakly dissociated, the exchange reaction (Eq. 1) remains incomplete, and the pH of the solution increases progressively even during the early stages of titration (Fig. 9, curve b). A sharp rise is noticed, however, when the resin is converted completely to the Na^+ form.

In both cases, the total capacity of the resin can be read from the titration curves and corresponds to the amount of sodium hydroxide that produces the sharp rise in pH. In Figure 9, Amberlite IR 120 has a total capacity of 2 meq/mL, whereas Amberlite IRC 86 has a capacity > 4 meq/mL.

Similar considerations apply to anion-exchange resins.

5.2. Mono – Monovalent Exchange

The law of mass action applied to the reaction

$$R^-H^+ + Na^+ \rightleftharpoons R^-Na^+ + H^+$$

gives

$$\frac{[\underline{Na}^+]\,\underline{\gamma}_{Na}}{[\underline{H}^+]\,\underline{\gamma}_{H}} = K\,\frac{[Na^+]\,\gamma_{Na}}{[H^+]\,\gamma_{H}} \qquad (2)$$

where $[Na^+]$ and $[H^+]$ are the equivalent concentrations in the liquid phase and γ_{Na} and γ_H are the corresponding activity coefficients. The concentrations and coefficients for the resin are underlined. Thus,

$$K \cdot \frac{\gamma_{Na}}{\gamma_H} \cdot \frac{\underline{\gamma}_H}{\underline{\gamma}_{Na}} = \frac{[\underline{Na}^+]}{[\underline{H}^+]} \cdot \frac{[H^+]}{[Na^+]}$$

The activity coefficients may be assumed constant, so that

$$\frac{[\underline{Na}]}{[\underline{H}]} = K_H^{Na} \cdot \frac{[Na]}{[H]}$$

(the + signs are omitted for simplicity). The parameter K_H^{Na} is known as the *selectivity coefficient* for the Na^+/H^+ exchange.

Selectivity coefficients differ for each pair of ions because the affinity of the resin for an ion is governed by the size of its hydrated form. The larger the ion, the more the resin bead must expand to accommodate it. Expansion is opposed by the restraining cross-links, so that large ions require a greater force to penetrate the resin than small ones.

Table 4. Relative selectivities of sulfonic resins for cations

Cation	Degree of cross-linking, % DVB			
	4	8	12	16
Monovalent				
H *	1.0	1.0	1.0	1.0

Propionate	2.6	0.3
Fluoride	1.6	0.3

* Reference value

The degree of cross-linking in resins is not uniform, so that an ion entering a resin first seeks the most favorable regions. All exchange reactions become less favorable as they progress toward completion. The practical effects of this general phenomenon on the exchange rate, exchange capacity, and leakage from resins are considered in Chapter 7.

5.3. Mono – Divalent Exchange (Water Softening)

In the exchange reaction

$$2\,R^-Na^+ + Ca^{2+} \rightleftharpoons (R^-)_2Ca^{2+} + 2\,Na^+$$

the law of mass action gives

$$\frac{[\underline{Ca}]\,\underline{\gamma}_{Ca}}{[\underline{Na}]^2\,\underline{\gamma}^2_{Na}} = K\,\frac{[Ca]\,\gamma_{Ca}}{[Na]^2\,\gamma^2_{Na}}$$

If the activity coefficients are constant, then

$$\frac{[\underline{Ca}]}{[\underline{Na}]^2} = K^{Ca}_{Na}\,\frac{[Ca]}{[Na]^2}$$

The equivalent fraction X_i of an ion i in a solution with a total concentration of ions $[C]$ is defined by

$$X_i = [i] \,/\, [C]$$

Similarly, the equivalent fraction of ion i in the resin is

$$[\underline{X}_i] = [\underline{i}] \,/\, [\underline{C}]$$

The total concentration of ions in the resin $[\underline{C}]$ (in equivalents per liter) is the same as the total capacity (defined in Section 3.2).

In exchange involving only two ions (e.g., Na^+ and Ca^{2+}), the following equations apply to the solution:

$$[C] = [Na] + [Ca]$$

$$X_{Na} + X_{Ca} = 1$$

Similar equations hold for the resin. Equation (2) thus becomes

$$\frac{\underline{X}_{Ca}}{(1-\underline{X}_{Ca})^2} = K^{Ca}_{Na}\cdot\frac{[\underline{C}]}{[C]}\cdot\frac{X_{Ca}}{(1-X_{Ca})^2} \qquad (3)$$

where $[\underline{C}]$ is constant and K^{Ca}_{Na} is approximately constant at low concentrations. Equation (3) shows that as the solution becomes more dilute (decreasing C) with a constant fraction of calcium ($\underline{X}_{Ca}$ constant), X_{Ca} increases. The resin takes up more calcium as the total cation concentration of the solution decreases. This effect is illustrated in Figure 10, which shows the equilibrium curves for a given resin at various total concentrations of the solution. Each point on a curve corresponds to the equivalent fraction of calcium in the resin at equilibrium, i.e., the curve gives the proportion of active sites in the resin in Ca^{2+} form as a function of the proportion of calcium in solution. These curves are called *ion-exchange isotherms*.

Figure 10. Mono – divalent equilibrium curves for Na^+ – Ca^{2+} solutions of different total concentration
Total concentration of Na^+ and Ca^{2+}, eq/L: a) 0.005; b) 0.01; c) 0.1; d) 1; e) 5

Water Softening. For water with a total salinity of 5 meq/L, i.e. $[C] = 0.005$ N, Figure 10 shows that water containing only 5 % Ca^{2+} ($X_{Ca} = 0.05$ or [Ca] = 0.25 meq/L) is in equilibrium with a resin loaded with 95 % calcium ($\underline{X}_{Ca} = 0.95$). In other words, the resin is capable of removing calcium from the water even if the concentration accounts for only 5 % of total cations ($X_{Ca} = 0.05$), as long as the resin contains more than 5 % sodium ($\underline{X}_{Ca} < 95$ %). At high concentrations, the affinity of the resin for calcium over sodium decreases until sodium becomes favored. This is the effect that makes regeneration of the resin possible.

Figure 11 shows the complete softening cycle and regeneration with 12 % brine (ca. 2 N NaCl) using curves representing successive equilibrium states of the system. At the starting point O, all of the resin is in the sodium form. The water, with a total sodium and calcium content of 5 meq/L (0.005 N), comes in contact with the resin, and establishment of an equilibrium leads to the uptake of calcium by the resin and its removal from the water. The first upward-pointing arrow on the curve indicates the displacement of the equilibrium. A new equilibrium is then established at P′ where the resin loaded with 20 % calcium is in equilibrium with completely softened water. The equilibrium then shifts to P, where resin loaded with 40 % calcium is still in equilibrium with completely softened water, and finally to Q where the resin loaded with 90 % calcium is in equilibrium with water which is about 98 % softened ($X_{Ca} = 0.02$) and therefore contains $0.02 \times 5 = 0.1$ meq/L of calcium. At this point, known as the end point, a new stage of the process is initiated to regenerate the resin (to continue as before would lead to the removal of less calcium). The system is displaced to point R on the other curve as the sodium chloride concentration changes from 0.005 to 2 N. At R, the resin is in equilibrium with a solution containing about 95 % calcium and therefore tends to release calcium ions so as to produce this concentration in the liquid. In this regeneration process, the resin is converted continuously into the sodium form by exchanging the calcium ions adsorbed during the first stage for sodium ions from the regenerating brine.

Figure 11. Successive equilibria in the water-softening cycle

As the system moves toward the bottom of the curve, the equilibrium becomes less favorable: at R, 95 % of the sodium chloride in the solution is used up in regeneration of the resin (because $X_{Ca} = 0.95$), whereas at point S the proportion is already less than 60 % and at point T, 25 %. At the latter point, the resin is 60 % regenerated ($\underline{X}_{Ca} = 0.4$) and the process stops because any attempt to reach point O would need increasing amounts of brine, only a small proportion of which would be used in actual regeneration. The resin is therefore rinsed at point T and another new stage is initiated by displacing the system to P and beginning a second cycle in which the

water is again almost completely softened. All subsequent cycles follow the path PQRT.

The regeneration efficiency (percentage of brine exchanged) can be evaluated at each point on the curve RSTO. Between R and T the mean regeneration efficiency is 60 %.

Regeneration was carried out between $\underline{X}_{\mathrm{Ca}} = 0.9$ and 0.4, so that half the total capacity of the resin was used. With a total capacity of 2 eq/L, the operating capacity would thus be 1 eq/L. A regeneration efficiency of 60 % is assumed, 1/0.6 = 1.67 eq of sodium chloride would be used, i.e., 97.5 g per liter of resin.

Figure 12. Ion-exchange isotherms for mono – monovalent ions

5.4. General Case

In the general exchange reaction between ions A and B of ionic valences a and b, respectively, the *selectivity coefficient* $K_{\mathrm{A}}^{\mathrm{B}}$ is defined as

$$K_{\mathrm{A}}^{\mathrm{B}} = \frac{[\underline{\mathrm{B}}]^b}{[\underline{\mathrm{A}}]^a} \cdot \frac{[\mathrm{A}]^a}{[\mathrm{B}]^b}$$

$K_{\mathrm{A}}^{\mathrm{B}}$ depends on experimental conditions such as concentration and temperature.

Another useful quantity is the *separation factor*, defined as

$$\alpha_{\mathrm{A}}^{\mathrm{B}} = \frac{[\underline{\mathrm{B}}]}{[\underline{\mathrm{A}}]} \cdot \frac{[\mathrm{A}]}{[\mathrm{B}]} = \frac{\underline{X}_{\mathrm{B}}}{1-\underline{X}_{\mathrm{B}}} \cdot \frac{1-X_{\mathrm{B}}}{X_{\mathrm{B}}}$$

For mono – monovalent exchange, the separation factor $\alpha_{\mathrm{A}}^{\mathrm{B}}$ and selectivity coefficient $K_{\mathrm{A}}^{\mathrm{B}}$ are identical and practically independent of the total salt content. For mono – divalent exchange, $\alpha_{\mathrm{A}}^{\mathrm{B}}$ is a function of the term $K \cdot [\underline{C}]/[\mathrm{C}]$. A separation factor $\alpha_{\mathrm{A}}^{\mathrm{B}}$ greater than unity means that the resin will take up ion B in preference to ion A.

Figure 12 shows ion-exchange isotherms for two monovalent ions A and B. The upper curve ($\alpha = 2$) represents a case in which the resin has a higher affinity for B than for A; the lower curve ($\alpha = 0.2$) represents the opposite case. For any point on a given isotherm, the ratio between the two hatched areas is equal to the separation factor α.

In many cases, simple selectivity calculations show whether proposed ion-exchange processes will function [17], [18].

6. Exchange Kinetics

6.1. Principles [19], [20]

Mass action equations apply only to systems in equilibrium. In industrial practice where a solution flows through the resin, equilibrium is not necessarily reached and the results are influenced by kinetic considerations.

In fully ionized systems, the rate-determining step of ion exchange is the diffusion of the mobile ions toward, from, and in the resin phase, rather than the chemical reaction between fixed ions of the resin and mobile counterions. If a cation-exchange resin with negative fixed ions (e.g., sulfonate ions) is used as an example, the cation concentration in the resin is much greater than that in solution. However, any cations diffusing out of the resin into the dilute solution create a net negative charge in the solid phase and a net positive charge in solution. The resulting potential difference is called the *Donnan potential*; it prevents anions from penetrating the (negatively charged) resin. This phenomenon is called *Donnan exclusion.* Therefore, the co-ion (i.e., the anion in the case of cation exchange) does not participate in the ion-exchange process.

Figure 13 illustrates the uptake of Na^+ ions by a bead of H^+-form resin. The bulk solution contains a large excess of available Na^+ ions, with an effectively constant concentration. A static layer of solution, known as the *Nernst film*, surrounds the bead. This film is defined such

that it is unaffected by convection (i.e., flow) around the bead; ion transport takes place by diffusion only. Strong convection (i.e., high flow rate) decreases film thickness. The ion concentration is practically constant outside the Nernst film, and a concentration gradient occurs within it (Fig. 14).

Figure 13. Diffusion through a film and inside a particle

Figure 14. Nernst film

Diffusion through the film and in the solid phase occurs at different rates and two steps may be rate-determining:

1) Diffusion of ions within the resin (*particle diffusion*)
2) Diffusion in the Nernst film (*film diffusion*)

The slower step controls the overall ion-exchange rate. A criterion has been established by HELFFERICH [19] to determine which process is rate-determining:

$$H = (\underline{C}\underline{D}\delta / CDr) \cdot \left(5 + 2\alpha_{\mathrm{A}}^{\mathrm{B}}\right)$$

where

C = total ion concentration in solution
$\underline{C}$ = total ion concentration in the solid phase (total capacity)
D, $\underline{D}$ = diffusion coefficients
H = Helfferich constant
δ = thickness of Nernst film
r = radius of ion-exchange bead
α = separation factor (defined in Section 5.4)

When $H \gg 1$, film diffusion is rate-limiting; when $H \ll 1$, particle diffusion is rate-limiting.

The definition of H shows that film diffusion is favored by the following:

High resin capacity $\underline{C}$
Thick Nernst film δ (i.e., low flow rate)
Low concentration C in solution
Small resin beads
High selectivity (high α)

In general, forward and reverse exchange rates differ (Fig. 15). In this example of H^+/Na^+ exchange in a conventional strongly acidic cation-exchange resin, forward exchange (uptake of Na^+ ions) is faster than reverse exchange (regeneration). Because the H^+ ion generally is more mobile, exchange is faster when the faster ion is in the resin initially. The rates of sodium – calcium exchange are several times slower.

Figure 15. Forward and reverse exchange rates in a polystyrene sulfonic resin
a) Conversion from H^+ to Na^+ ; b) Conversion from Na^+ to H^+

For a given ion, mass-transfer flux through the film can be described by Fick's law:

$$J = -D \cdot \mathrm{grad} C$$

where

J = ion flux, mol s^{-1} cm^{-2}
grad C = ion concentration gradient, mol/cm^3
D = diffusion coefficient cm^2/s

When D is constant, the ion concentration independent of C, and the concentration gradient linear, the relationship becomes

$$J = k \cdot (C_1 - C_0)$$

where k is the *mass-transfer coefficient* (cm/s) given by D/δ. Measurement of the mass-transfer coefficient of new and used resins can provide useful information about their ability to operate under critical conditions [21].

Diffusion in the resin phase is always slower than that in solution, due to the obstruction created by the resin matrix. Highly cross-linked materials have smaller diffusion coefficients.

For a comprehensive treatment of diffusion and rate laws in ion exchange, the reader is referred to [19], [20]. The remainder of this chapter deals with practical consequences of the above kinetic principles.

6.2. Kinetic Curves

As with ionic equilibria, exchange kinetics are difficult to appreciate from a purely mathematical point of view. However, exchange rates for different resins can be compared under the same conditions.

Figure 16. Kinetics of Duolite A 101U in uranium extraction

Rate of Ion Uptake (Exhaustion Rate). The exhaustion rate of a resin through which a given solution flows is measured under standard conditions. In the general case of a single ion species, the exhausted fraction X_i of the resin is plotted vertically against time (Fig. 16). The example illustrates the recovery of uranium from a sulfuric acid leaching solution in a stirred tank with strongly basic exchangers in the sulfate form. Duolite A 101U is a high-capacity polystyrene material.

Kinetic Leakage. The concentration of ions that is not taken up by the resin but passes into the treated solution is termed the ion leakage. Kinetic ion leakage can be measured as a function of specific flow rate, which is the ratio of the flow rate of the solution to be treated to the volume of resin. The specific flow rate is expressed as cubic meters of solution per hour per cubic meter of resin or as bed volume (BV) per hour.

Figure 17. Kinetic leakage: conductivity vs. flow rate for two resin mixtures at two concentrations
a) Used cation resin, NaCl 16 mg/L; b) New cation resin, NaCl 16 mg/L; c) Used and new resins, NaCl 1.7 mg/L

In the example shown in Figure 17, new and used macroporous strongly acidic cation-exchange resins were tested for their ability to remove sodium from dilute sodium chloride solutions percolated through a mixed bed made of the cation resin and of a new, highly regenerated nuclear-grade anion resin. The conductivity of effluent water was measured. Both mixtures give identical low leakage for the more dilute sodium chloride solution (1.7 mg/L, curve c). However, the mixture containing used cation resin is more sensitive to the flow rate than that with new cation resin when the sodium chloride

concentration is increased to 16 mg/L (curves a and b); both mixtures then become strongly sensitive to flow rate.

This type of kinetic test is useful to assess resin performance, particularly when very high-purity water is required [22], [23].

6.3. Strongly Acidic or Strongly Basic Resins

6.3.1. Film Diffusion

At concentrations up to 10 meq/L and flow rates up to 120 m/h used in water treatment, diffusion rates through the resin mass are much greater than through the surrounding film. The film thus controls the rate of exchange, and the process exhibits film-controlled kinetics. When sodium chloride solution passes through a column of resin, originally in H^+ form, the concentration of the ion under consideration in the emergent liquor exhibits variations of the form shown in Figure 18.

Figure 18. Film kinetics: exhaustion curves and volumes passed at maximum leakage
For explanation see text.

If the flow rate is slow enough, equilibrium is established as the solution reaches a new layer of the resin. The concentration in the emergent liquor is represented by the curve OFP. At F, the breakthrough point, the concentration reaches its maximum permitted value and flow stops. If it were continued up to P where the concentration in the emergent liquor equals that of the raw solution, the resin would be 100 % exhausted.

In industrial practice, flow is stopped when the concentration of the ion under consideration in the emergent liquor reaches a small fraction (e.g., 1 %) of the concentration in raw solution. At F, a volume A of the solution has flown through the column. The capacity used is given by the area OFA′Z, which differs very little from the area OFPZ representing the total capacity of the resin.

Figure 18 can also be taken to represent the progress of the exhaustion wavefront through a resin column. In the slow flow described above, the wavefront is only slightly diffuse, each successive layer of resin being almost completely exhausted before leakage occurs. As flow rate increases, equilibrium is no longer reached and the exhaustion curve OGQ is obtained. If the process is continued beyond the breakthrough point G as far as Q, the area OGQZ gives another measure of the total capacity of the resin. If, however, the process is stopped at G, the capacity used is only that given by OGB′Z, which is less than the total capacity.

If the flow rate is increased further, a curve such as OHR is obtained, which has a still smaller operating capacity at the new breakthrough point H.

Because the Nernst film thickness is an inverse function of flow rate, the film becomes thinner as the flow rate increases. Thus, doubling the flow rate does not mean that the leakage curve is spread out over twice the distance. In film-controlled kinetics, capacity depends very little on the rate of presentation of ions or kinetic load (i.e., the product of flow rate and concentration in the solution to be treated). In the complete absence of kinetic effects, the operating capacity is entirely independent of flow rate; therefore, the volume of the exhaustion stage is inversely proportional to the ionic concentration. As described in Section 5.3, the operating capacity of a strongly acidic resin depends mainly on the amount of regenerant. For a given quantity of regenerant, a corresponding capacity is available which is less than the total capacity.

If the exhaustion time is too short (i.e., if resin volume is small and flow rate per unit volume is high), the operating capacity is less than the available capacity. This reduction in operating capacity (which is mainly confined to strongly and weakly basic anion resins) can increase as the resin ages due to partial blocking of its pores with organic matter absorbed during several years of service. Fouling of this type reduces ion diffusion rates. In designing a

demineralizing plant, the anion-exchange column should have sufficient capacity to allow the plant to run for at least 8 h at the maximum loading rate.

6.3.2. Particle Diffusion

As the concentration of ions in solution increases, the mass-transfer rate through the film rises until it exceeds the diffusion rate through the resin beads. Diffusion through the resin then becomes the controlling factor, and the system is said to exhibit particle-controlled kinetics. This condition occurs mainly during regeneration of resins with solutions having concentrations between 1 and 3 N.

Breakthrough curves are similar to those in Figure 18, except that the length of the wavefront is a linear function of flow rate. Because of the high concentration gradient through the resin, the whole process is much faster than the exhaustion stage. Virtually complete equilibrium can be achieved in 15 min, but if a shorter regeneration time is used, operating capacity can be significantly reduced. Nevertheless, small automatic water softeners sometimes have brine injection times as short as 5 min.

6.4. Weakly Acidic or Weakly Basic Resins

Weakly acidic or weakly basic resins are not fully ionized in the regenerated form. As a result, the adsorption process involves not only diffusion through the resin but also the formation or destruction of covalent bonds, which are slower processes. The exchange rate of these resins is therefore controlled by slow particle diffusion and the resin cannot be exhausted as quickly as with strongly ionized materials. Weakly acidic and weakly basic resins are said to have slow kinetics: their capacity depends strictly on the rate of presentation of ions.

As shown in Figure 19, the carboxylic resin Amberlite IRC 86 requires a cycle time of over 24 h to utilize its full capacity (in this example, the ions to be removed from solution have a concentration of 5 meq/L). In practice, usually less than half the total capacity of weakly acidic resins is utilized. The kinetic effect is not as dramatic for weakly basic resins, which are usually operated at ca. 75 % of their total capacity.

Figure 19. Effect of cycle time on usable capacity for a weakly acidic cation resin (a) and two weakly basic anion resins (b, c)
a) Amberlite IRC 86 (weakly acidic); b) Amberlite IRA 67 (weakly basic, acrylic); c) Amberlite IRA 96 (weakly basic, styrenic)

7. Practical Results of Ion-Exchange Equilibrium and Kinetics

As shown in Chapter 6, under normal conditions the exchange process is always incomplete in both the service and the regeneration stages, which means that the total capacity of the resin can never be fully used.

7.1. Operating Capacity, Regeneration Efficiency, and Regenerant Usage

Calculation of operating capacity must take into account the following:

Raw water analysis
Required quality of treated water (acceptable leakage)

Service flow rate
Temperature of water to be treated
Type and amount of regenerant
Regeneration flow rate
Regenerant temperature
Required duration of cycle

The concept of operating capacity has been introduced in Section 3.2 and developed in Section 5.3 for the special case of water softening ($Na^+ - Ca^{2+}$ equilibrium), in both instances starting from 100 % regenerated resin. In practice, this is seldom the situation because an enormous amount of regenerant would be required to remove all the ions from the resin that were taken up during the previous cycle. The variable that has the greatest effect on operating capacity is therefore the amount of regenerant used.

Regeneration efficiency is defined as the ratio of the operating capacity to the amount of regenerant used; both expressed in equivalents per liter. The reciprocal of this efficiency is known as the *regenerant usage* or *regenerant ratio* and is always >1. In practice, these quantities are often expressed as percentages.

Figure 20. Operating capacity of a strongly basic type 1 resin as a function of regenerant dosage (caustic soda)
Numbers on the curves indicate percentage of regenerant efficiency.

With most strongly acidic or strongly basic resins more than 60 % of their total capacity is seldom used. As an example, the total capacity of the strongly basic type 1 resin shown in Figure 20 is ca. 1.2 eq/L. A basic operating capacity of 0.46 eq/L can be obtained by using 60 g of caustic soda per liter of resin (1.5 eq/L). In this case, the regeneration efficiency (0.46/1.5) barely exceeds 30 %. By doubling the amount of regenerant, a basic operating capacity of 0.615 eq/L can be achieved: this is only one-third greater than before, and regeneration efficiency falls to 21 %. Thus, such a resin is seldom operated at more than 50 % of its total capacity. However, these very strongly basic type 1 materials are less easily regenerated than type 2 resins and therefore yield a lower operating capacity for the same amount of regenerant than the latter. Weakly acidic and weakly basic resins, on the other hand, can be completely regenerated, but their operating capacity is limited by their poor kinetics (Section 6.4).

Figure 21. Ion leakage due to self-regeneration in a coflow regenerated column
For explanation see text.

7.2. Permanent Leakage

Strongly Acidic and Strongly Basic Resins. When strongly basic or strongly acidic resins are returned to service after regeneration, they are only partially regenerated. When coflow operation is used (i.e., when flow is in the same direction in the service and regeneration stages), the most poorly regenerated layer is usually the lower one through which the treated solution emerges. This affects the quality of the treated solution due to self-regeneration. In practice, the bed does not consist of two distinct (completely regenerated, completely exhausted) regions, but has a continuously varying level of regeneration along the column. Figure 21 shows the exchange reactions that occur in the column during the

service stage, in which salts from the solution (represented here by NaCl) are retained by the regenerated resin layers. Each Na^+ ion that is taken up ejects an H^+ ion from the resin. The H^+ ions move down the column and reach a region where the resin is only partially regenerated. Reverse exchange then takes place (self-regeneration), leading to leakage of Na^+ ions into the treated water.

Figure 22 shows the operating capacity (A) and sodium leakage (B) of Amberlite IR 120 (a standard, gel-type, strongly acidic cation-exchange resin) as a function of regenerant level.

Figure 22. Capacity (A) and sodium leakage (B) of a standard strongly acidic cation resin (Amberlite IR 120) regenerated in coflow mode.
Sodium (NaCl) content with respect to total cation concentration: a) 100 %; b) 50 %; c) 25 %Flow rate, 10 BV/h; total salinity of raw water, 10 meq/L; acid dosage expressed as 100 % HCl per liter of resin; water temperature, 20 °C.

In raw water, the main cations are usually sodium, calcium, and magnesium. The selectivity of strongly acidic resins for these cations increases in the order $Na^+ < Mg^{2+} < Ca^{2+}$ (Section 5.2). Therefore, chromatographic separation occurs in the resin column, and the sodium ion is the first to emerge in the treated solution, both other cations being more strongly held by the resin. This explains the high leakage obtained for water having only sodium as a cation (Fig. 22 B, curve a).

Because the quality of demineralized water is generally expressed in terms of its electrical conductivity, sodium leakage from the cation-exchange column is the main contributor to the conductivity of treated water. A sodium leakage of 1 mg/L corresponds to 9 µS/cm conductivity (as NaOH). In coflow regenerated systems, the level of regenerant is chosen according to the desired conductivity. For high-sodium water, the only way to obtain low leakage is to use counterflow regeneration (see Section 8.2).

Weakly Acidic and Weakly Basic Resins. Weakly acidic and weakly basic resins are almost 100 % regenerated at the start of the service stage, but their exchange rate is relatively low so that some ions are not taken up and pass through the bed (i.e., kinetic leakage; see Section 6.2).

7.3. Water Analysis

Calculations for designing water treatment plants that use ion-exchange resins involve some simple concepts related to the composition of the raw water.

Units. Ion concentration is usually measured in equivalents per liter. The following units are also used to express ionic concentrations in water:

the French degree: 1° f = 0.2 meq/L
the German degree: 1° dH = 0.357 meq/L (which corresponds to 10 mg of CaO per liter)

The following units are used in Great Britain and other English-speaking countries:

1 g of $CaCO_3$ per liter = 0.02 eq/L
1 mg of $CaCO_3$ per liter = 0.02 meq/L

Although resin capacities are internationally expressed in equivalents per liter, in the United

States capacity values are widely given in kilograins (kgr) where 1 kgr as calcium carbonate per cubic foot corresponds to 0.0458 eq/L.

Water Composition. For ion-exchange calculations, the exact composition of the solution to be treated must be known. The composition of a typical water is given in Figure 23. The total concentration of all the anions and cations in solution is known as the *total dissolved solids* (TDS). Ions normally encountered in water treatment are the cations Na^+, Ca^{2+}, Mg^{2+}, and the anions OH^-, CO_3^{2-}, HCO_3^-, Cl^-, NO_3^-, SO_4^{2-}. Other ions may be present (K^+, NH_4^+, Mn^{2+}, Fe^{2+}), but their concentration in natural water is usually very low. For ionic equilibrium, the total cation and anion concentrations measured as equivalents per liter must be equal.

Figure 23. Composition of water

Both Ca^{2+} and Mg^{2+} ions (and, possibly, Fe^{2+} and Mn^{2+}) are classified as ions producing hardness, and their concentration gives the *total hardness* (TH) measured in milliequivalents per liter. In water softening, Ca^{2+} and Mg^{2+} are exchanged for Na^+. The Cl^-, NO_3^-, and SO_4^{2-} ions are grouped together, and their total concentration is called the *equivalent mineral acidity* (EMA), or *free mineral acidity* (FMA) after cation exchange.

The total concentration of OH^-, CO_3^{2-}, and HCO_3^- ions, measured in equivalents per liter gives the *total alkalinity* (TAlk). This is often referred to as m-Alk or the *m* value (alkalinity to methyl orange):

$$\text{TAlk} = m = \left[HCO_3^-\right] + \left[CO_3^{2-}\right] + \left[OH^-\right]$$

When TH exceeds TAlk, the difference (TH−TAlk) is called the *permanent hardness,* whereas TAlk is known as the *temporary (or bicarbonate) hardness*. When TH is lower than TAlk, only temporary hardness (no permanent hardness) exists. For water with alkaline pH values, the *caustic alkalinity*, usually described as p-Alk or the *p* value (alkalinity to phenolphthalein) is measured separately.

Carbonate Equilibrium.

The *p* value includes all anions with a p$K > 8.3$, i.e., in practice the OH^- ions and a value arithmetically equal to half the total carbonate present because CO_3^{2-} is first neutralized to HCO_3^-, which itself has a pK of only 6.7:

$$p = \left[OH^-\right] + \left[CO_3^{2-}\right]/2$$

In a demineralization system, where the first step is usually cation exchange, ions of *p* alkalinity must not be considered in the anion-exchange balance, because they are neutralized by the H^+ ions produced in the cation-exchange part of the process:

$$OH^- + H^+ \longrightarrow H_2O$$

$$CO_3^{2-} + 2H^+ \longrightarrow CO_2 + H_2O$$

As demonstrated in Section 4.2, carbon dioxide is taken up by the strongly basic resin as monovalent bicarbonate, but must be regenerated as a divalent species:

$$RHCO_3 + 2\,NaOH \longrightarrow ROH + Na_2CO_3 + H_2O$$

Because in the series OH^-, CO_3^{2-}, HCO_3^-, and CO_2, only two adjacent species can coexist in water, raw water does not contain free carbon dioxide when *p* is positive.

In practice, the equivalent concentration of carbon dioxide to be considered after cation exchange (and before the degasifier, if any) is

$$[CO_2] = m - p + [\text{free}\,CO_2]$$

The case in which $p = 0$ is the most common one, except when the raw water is lime-decarbonated. Besides, free carbon dioxide exists only with a pH close to or lower than neutral.

The concentrations of nonionized substances must also be known; these include free silicon

dioxide and carbon dioxide. The amount of organic substances present in the raw water should be considered on the anion side, because they are mainly acidic. Concentration is usually expressed in terms of the quantity of potassium permanganate needed to oxidize these substances (milligrams of $KMnO_4$ per liter of solution). The amount of organic matter determines the choice of anion-exchange resin (see Section 10.1). The permanganate value obtained in the oxidizing test depends on the test method. Here, oxidation is assumed to be performed with 0.0125 N potassium permanganate in the presence of sulfuric acid, the solution being boiled for 10 min. The composition of a typical water is given in Figure 23.

Fouling with Organic Material. The most common organic constitutents in natural waters are the high molecular mass carboxylic acids, humic and fulvic acid. These large molecules enter the ion-exchange resins and are trapped in the most highly cross-linked regions, their chains becoming tangled with the resin matrix. This eventually reduces the capacity of anion exchangers. Rinsing becomes more difficult, and problems arise with the quality of treated water because the carboxylic character of the organic matter means that, as the pH varies, caustic soda is initially taken up and then leached out. The problem is aggravated by synthetic ionic surfactants.

Although qualitative and quantitative assessment of organic materials is difficult, their concentration is usually expressed in milligrams of potassium permanganate required per liter of water to oxidize them under the given conditions. The *fouling factor N* is the quantity of organic matter (in milligrams per liter of $KMnO_4$) divided by the total anion concentration (in milliequivalents per liter).

Anion resins can be listed in order of their resistance to fouling, starting with the least resistant:

Polystyrene, gel type 1	2
Polystyrene, macroporous type 1	4
Polyamine, weakly basic	4
Polystyrene, gel type 2	6
Polystyrene, macroporous type 2	8
Polyacrylic, strongly basic	20
Polystyrene, weakly basic	20
Polyacrylic, weakly basic	40

These values merely indicate the fouling risk of each individual resin and give no information about the amount of organic material taken up. Anion resins, even those with high fouling resistance, do not remove all organic matter from the influent solution. Reversible uptake can range from 20 to 80 %; a reasonably safe figure is 50 %.

If N is too large (e.g., > 8 for a strongly basic polystyrene material), the risk of fouling can be reduced by increasing the volume of resin. The working capacity of the resin will be less than its potential operating capacity. Weakly basic resins can also protect strongly basic resins against fouling.

7.4. Calculations in the Design of Ion-Exchange Plants for Water Purification

General Method. The various types of combination process, the criteria used in choice of resin, and the recommended operational conditions are considered in Chapter 9. The operating capacity for water softening is greater when the amount of regenerant is large, the sodium ion (self-regenerant) concentration is low, and the flow rate is low.

Resin manufacturers provide standard charts and curves for each type of resin, enabling calculations to be made of the volume of each resin, amount of regenerant, operating capacity, and leakage. The starting point is normally provided by a curve that applies to standard conditions, and corrections are made for each condition that differs from the set standard. The method of calculation is too complicated to be described here; only the main factors are considered.

Weakly acidic carboxylic resins have a very high capacity for divalent ions (Ca^{2+} and Mg^{2+}): they remove temporary hardness (see Section 7.3) and are normally used only when the temporary hardness is high and the total hardness of the water is even greater (TH > TAlk). Their relatively slow exchange rate means that they are very sensitive to the specific flow rate.

Regeneration is carried out with an amount of acid calculated to be slightly in excess of the design capacity, with a regenerant ratio on the order of 105 – 110 %. These resins are therefore very efficient.

Strongly Acidic Sulfonic Resins. In hydrogen exchange, capacity depends on the type of acid used for regeneration: hydrochloric acid is the most efficient because sulfuric acid is not completely dissociated at the concentration normally used. In addition (this also applies to carboxylic resins), if the resin has taken up a lot of calcium, the sulfuric acid must be highly diluted to avoid precipitation of calcium sulfate during regeneration. The amount of regenerant is chosen according to the permitted ion leakage: in other words, it depends on the permissible level of electrical conductivity in the treated water (see Section 7.2). The greater the amount of regenerant, the lower is the electrical conductivity and the greater is the operating capacity (see Fig. 22). The operating capacity of the resin depends on the cation composition of the water, more in relation to proportions than to absolute values. Reference should be made to manufacturers' curves.

Weakly basic resins also have slow kinetics and are rate-sensitive. In addition, their capacity depends on the composition of the water, increasing as the concentration of strong acids decreases. Only small quantities of weak acids are removed. However, carbon dioxide improves the capacity of weakly basic styrene resins so that, if an atmospheric degasser is used it should be located between the weakly basic and strongly basic exchange steps. Weakly basic acrylic resins have a higher pK value, so that they effectively remove carbon dioxide from water, and the benefit of the degasifier is lost if it is located downstream.

The quantity of regenerant normally used is on the order of 130 % of the operating capacity of the resin.

Strongly basic resins remove strong and weak acids. Because the uptake of silica is poorer than that of other anions, it is the first to "leak". The regenerant level thus depends on the acceptable silica leakage. In addition, because silica has a tendency to polymerize on the resin, regenerating with hot sodium hydroxide is sometimes worthwhile. However, only type 1 materials withstand high temperature (see Section 3.3).

In practice, regenerant requirements are from 150 to ca. 500 % (sometimes > 1000 % when the strongly basic resin is preceded by a weakly basic one), so the efficiency of these resins is only moderate. However, a new type of strongly basic resins was developed by Duolite International, Bayer, and Rohm and Haas in the mid 1980s. These are partially quaternized weakly basic resins, which thus exhibit a strong base capacity of ca. 40 % (i.e., enough to efficiently remove silica from waters containing up to about 15 % SiO_2), whereas they offer a regenerability close to that of weakly basic resins. Examples of such resins are Amberlite IRA478 and Lewatit AP246.

Calculation of Resin Volume. From the calculated operating capacities, the volume of each type of resin can be determined as a function of the operating time chosen between two regenerations:

$$V = (Q \cdot t \cdot S) / C$$

where

V = resin volume, m^3
Q = flow rate, m^3/h
t = operating time, h
S = salinity to be adsorbed by the resin, eq/m^3 of water or meq/L
C = operating capacity of the resin, eq/m^3 of resin

Service Water. The operating cycle for water treatment includes backwashing, regeneration, and rinsing stages, all of which consume water. The salinity of this service water is thus added to the ionic load of the production cycle and reduces resin capacity. The volume of resin must therefore be increased in proportion to the amount of service water used. The additional volume depends on the salinity of the raw water, which varies between 5 % (low-TDS water) and 35 % (semibrackish water).

Specific Flow Rate and Cycle Duration. The specific flow rate should not be too low because a very even flow must always be obtained; irregularities in flow may cause "channeling" in the resin bed, thereby impairing complete exchange. Too high a rate produces an excessive head loss. The specific flow rate Q/V should be between 4 and 40 BV/h. If this is not the case, the volume V must be appropriately adjusted by shortening or lengthening the operating time t.

7.5. Example of Calculation

In this section, the calculation of a system for demineralizing water, based on Amberlite resins is described. One solution of the problem is fully developed here, further options are discussed in Section 9.3 and column design in Section 10.2.

7.5.1. Principle

A set of curves for each type of resin is loaded into a computer, equipped with a program designed to yield the optimum system, given the characteristics required for the treated water and the consumption of regenerants. The calculation can also be carried out by hand. Basic data include the following:

- An analysis of the raw water
- Flow rate to be treated
- Required quality of the treated water
- Combination system required
- Types of resin to be used
- Length of the production cycle
- Types of regenerant
- Temperature of the caustic soda regenerant

The calculation leads to a determination of the volume, operating capacity, and regeneration rate for each resin. The diameter of each filter is also calculated as a function of its volume. A set of limiting criteria controls the calculation. Examples of these are the following:

1) The specific flow rates for each column must lie between 4 and 40 BV/h.
2) The linear velocity of flow should not exceed a value leading to high head loss across the bed; this linear flow rate is the ratio between the flow rate (in cubic meters per hour) and the area of the column (in square meters). The recommended head loss limit is 100 to 150 kPa.
3) The depth of the resin beds must be between 0.7 and 2.5 m.
4) The amounts of organic matter determine the choice of anion-exchange resins (see Section 7.3).

The above values should serve as guidelines for industrial water treatment. For special cases (e.g., condensate polishing or specific ion-exchange systems), the process limits are considerably different.

The demineralization of 80 m^3/h of water with a salt content of 8 meq/L can be used as an example. Each of the items is treated in the set of basic data (Table 6) and in the results of the calculation [demineralizing (Table 7) and polishing (Table 8) units].

7.5.2. Basic Data

Basic data are summarized in Table 6.

Analysis of Water. The water analysis must be available in detail and be ionically balanced.

Required Quality. Quality is expressed in terms of the electrolytic conductivity of the treated solution and the residual concentration of silica, which is important in boiler feedwaters.

Combination Process for Demineralization. The type of ion-exchange line and regeneration system is chosen according to the composition of the raw water, the flow rate to be processed, and the required water quality (see Chap. 9). Each of the pairs strong acid – weak acid and strong base – weak base resins is regenerated in thoroughfare, i.e., the weakly functional resin is regenerated with the excess from the strongly functional resin.

Role of Each Resin.

1) Amberlite IRC86, a weakly acidic cation resin, removes the temporary hardness, i.e. the calcium and magnesium ions, up to the limit of TAlk (4 meq/L).
2) Amberlite IR120, a strongly acidic cation resin, removes the rest of the cations ($Ca^{2+} + Mg^{2+} + Na^{+}$), i.e., $8 - 4 = 4$ meq/L.
3) Amberlite IRA96, a weakly basic anion resin, removes the EMA ($Cl^{-} + NO_3^{-} + SO_4^{2-}$), i.e., 4 meq/L.
4) Amberlite IRA458, a strongly basic anion resin, removes the other anions after degassing together with residual carbon dioxide (0.3 meq/L) and the silica (0.2 meq/L).

In addition, the two anion-exchange resins remove a considerable proportion of the organic matter contained in the water. Since the initial amount is quite large, a strongly basic polyacrylic material is chosen to avoid fouling.

Table 6. Examples of design data for a plant calculation

1) Water analysis, meq/L					
Ca^{2+}	5.0	Cl^-	3.0	P-Alk	0.5
Mg^{2+}	1.0	NO_3^-	0.0	M-Alk	4.0
$Na^+ + K^+ + NH_4^+$	2.0	SO_4^{2-}	1.0		
Total cations	8.0	EMA	4.0		
Silica	12 mg/L as SiO_2 (= 0.20 meq/L)				
Organic matter	10 mg/L $KMnO_4$				
Residual CO_2 (after degassing)	0.30 meq/L				
Water temperature	15 °C				
2) Production					
Running time (production) = 16 h	Net flow rate		80 m^3/h^3		
	Gross flow rate		82.7 m^3/h		
	Net throughput		1280 m^3		
	Gross throughput		1324 m^3		
3) Required water quality					
	Before polishing		After polishing		
Conductivity µS/cm	1.0		0.1		
SiO_2, ppm	0.1		0.01		

Table 7. Calculated results for the demineralization unit

Parameter	Amberlite resin type			
	IRC86	IR120	IRA96	IRA458

Pressure drop, kPa	38	53	49	40

7.5.3. Demineralization Unit

Duration of Production. The figure of 16 h was chosen for hydraulic reasons because the specific flow rate must not exceed 40 BV/h.

Total Ionic Load. This is the product of the gross production (percolated volume in cubic meters, taking into account the water required for regenerant dilution and rinse) and the salt content taken up by each exchange resin (in equivalents per cubic meter).

Operating Capacity. This is calculated for each resin from the curves supplied by the manufacturer.

Volume. The volume of each resin can be determined as a function of the operating time chosen between two regenerations from the formula:

$$V = (Q \cdot t \cdot S)\,/C$$

where $(Q \cdot t \cdot S)$ is the ionic load and C the operating capacity of the resin. The volume of resin is calculated by dividing the ionic load by the operating capacity.

Amount of Regenerant. This is determined from the manufacturer's curves as a function of the raw water composition and the required quality of the treated water. Both resin couples

(WAC – SAC and WBA – SBA) are regenerated in thoroughfare (see Section 9.3), i.e., the fresh regenerant first passes through the strong resin, then through the weak resin.

Regenerant Temperature. To improve elution of the silica, the caustic soda regenerant may be heated to 45 °C, but only if the strongly basic exchange resin is of type 1. For type 2 or polyacrylic materials, the temperature should not exceed 30 °C. Since Amberlite IRA 458 is a polyacrylic resin, regeneration at 25 °C is preferred.

Acid Concentration, Flow Rate, and Contact Time. Hydrochloric acid is generally used at a concentration of between 5 and 8 wt % and caustic soda at 4 wt %. Recommended contact time for all regenerants is between 15 and 60 min. If sulfuric acid is used, care must be taken that its strength is low enough to avoid precipitation of calcium sulfate on the cation exchange resins. Regeneration in this case is often carried out in several stages with sulfuric acid concentration increasing from 0.8 to 7 wt %.

Column Diameter. The diameter is chosen according to the volume of resin and flow rate so as to obtain a bed depth between 0.7 and 2.5 m of resin and a pressure drop of less than ca. 120 kPa across the bed.

Overrunning the Weakly Basic Resin. Calculating resin volumes on the basis of the ionic loads (see page 30) results in a large discrepancy between the volume of the weakly basic resin and that of the strongly basic resin. This is because the quantity of weak acids (carbon dioxide and silica) is small compared to that of strong acids. The volume of strongly basic resin would be less than 1000 L, and the corresponding specific flow rate (ca. 80 BV/h) would exceed the maximum recommended value of 40 BV/h. A better solution, always used in real projects, is to "overrun" the WBA resin. The volume of the WBA resin is made deliberately too small, so that part of the ionic load of the strong acids must be removed by the SBA resin, the amount of which, as a result, is made larger. In practice, the resin volumes are balanced in such a way that they are approximately equal. When the bicarbonate hardness in the feed water is very high (say 75 % or more of the dissolved solids), overrunning of the WAC resin is also possible.

Two Resins in One Column. As is discussed in in Chapter 10, modern ion-exchange systems use packed beds in which the WAC/SAC and the WBA/SBA resin couples are placed in the same column. This reduces considerably equipment costs.

Results of The Calculation. Using the overrun technique and packed bed design, and taking into account the higher capacity of the Amberjet resin and a specific rinse procedure that reduces the amount of waste, the final results of the calculation are summarized in Table 7.

Table 8. Calculated results for the polishing unit

Parameter	Amberjet 1200 H	Amberjet 4200 Cl
Volume per line, L	1000	1000
Production time, h	200	200
Max. throughput, m^3	16000	16000
Regeneration with	HCl	NaOH (25 °C)

Concentration, wt %	5.0	4.0
Suggested diameter, mm	1500	1500
Resin height, mm	1130	1130
Linear velocity, m/h	45.2	45.2
Specific flow rate, BV/h	40	40
Pressure drop, kPa	71	71

7.5.4. Polishing Unit

Calculated results for the polishing unit are listed in Table 8. The mixed bed for polishing (here a Triobed unit) is calculated in such a way as to have a specific flow rate of about 40 BV/h. Regeneration is carried out with 80 – 120 g of acid per liter of cation resin and 80 – 100 g of caustic soda per liter of anion resin.

The operating capacity is usually limited by the silica content, because the anion-exchange resin in the mixed bed almost entirely removes the silica that has leaked from the primary system. In addition, the proportion of anion-exchange resin in the mixture is generally selected between 50 and 65 %. The diameter of a mixed bed unit is calculated to give a bed depth between 0.9 and 1.5 m and a linear flow rate between 30 and 60 m/h. Because the influent to the mixed bed varies during the service run of the

primary line, the run length of the mixed bed is only approximate, and most users decide to regenerate their polishing unit after a fixed running time.

8. Industrial Use of Ion Exchange

The practical use of ion exchangers, based on the general principles discussed in the previous chapters, is described here. Although many examples refer to water treatment, other fluids are treated in a very similar way.

8.1. Description of the Ion-Exchange Cycle

Figure 24 shows a vertical section through a coflow ion-exchange column. The solution to be treated is introduced into the column through a distributor. It passes through the resin and emerges through a collector or collection system. In a conventional plant, the resin fills only half the available space so that the bed can be decompacted by an upward flow of water. This expands the resin and removes suspended matter and fragments of resin accumulated during the previous cycle.

Figure 24. An industrial ion-exchange column
a) Distributor; b) Resin; c) Collector

The ion-exchange cycle is divided into four stages:

1) exhaustion (or service),
2) decompaction (or backwash),
3) regeneration, and
4) rinsing.

Exhaustion (or Service). The solution to be treated passes through the resin bed and exhausts it. As soon as the quantity of ions taken up reaches the operating capacity (i.e., the breakthrough point) and leakage reaches a predetermined limiting value, the service stage is stopped.

Backwash. After the service stage, the resin is decompacted for about 15 min by an upward current of water. This treatment also removes any particles deposited on the surface of the bed, together with any fragments of resin. The bed is then allowed to settle.

Regeneration. The regenerant solution is introduced, usually at a concentration of a few percent, and slowly percolates through the bed. This takes about 15 – 60 min.

Rinsing. The regenerant is then displaced by water at a low flow rate until the resin bed contains no more than traces of regenerant. This displacement or slow rinse stage is followed by a rapid rinse stage at a higher flow rate to remove the last traces of regenerant. The concentration of the residual regenerant is measured at the end of the operation and, as soon as this falls to an appropriate limiting value, the next cycle begins. When water is being demineralized, the electrolytic conductivity of the emergent liquor is measured.

8.2. Methods for Overcoming Equilibrium Problems

Counterflow Regeneration [24], [25]. In the traditional method, the resin is regenerated by flow in the same direction as that during the service stage (coflow). Figure 21 illustrates the exhaustion of the bed in this case. For economically acceptable quantities of regenerant, the bottom of the bed is only partially regenerated, which results in high leakage (see Section 7.2). This effect is of major importance in the demineralization of water. The leakage problem can be overcome by regenerating in the reverse direction (i.e., from bottom to top). The

Figure 25. Effects of coflow and counterflow regeneration on the condition of resin beds during loading and regeneration Hatched areas indicate 100 % exhausted resin, and white areas, regenerated resin.

lowest resin layers reach equilibrium with fresh, uncontaminated acid and are therefore completely regenerated. This minimizes permanent leakage during the next cycle. Several counterflow regeneration systems are described in Section 10.2.2. Among these, some have an upflow exhaustion phase with downflow regeneration. The bed must be kept perfectly compacted when operating in upflow mode to maintain contact between the ions in solution and the resin beads.

Figure 26. Effects of coflow and counterflow regeneration on ionic leakage

Reverse flow regeneration is often called "countercurrent," which implies two streams flowing in the opposite direction. The terms "counterflow" or "reverse flow" are used here, both meaning only that the direction of percolation is reversed between service and regeneration.

The difference between coflow and counterflow regeneration is illustrated in Figure 25, and their effects on treated water quality are shown in Figure 26. Two-bed demineralization with counterflow regeneration produces water with a conductivity $\leq 2.0\,\mu$S/cm, even from feedwater with a high sodium content, and the consumption of regenerant is much lower than with coflow regeneration. Figure 25 also shows that in counterflow regeneration, ions taken up by the resin are desorbed over the shortest path instead of passing through the whole bed; the lower layers are always regenerated well.

In order not to disturb the arrangement of resin layers, the bed is only backwashed every 20 – 50 cycles.

Rinse Recycling. Considerable economy can be achieved by recycling the rinse water to remove traces of salts and regenerant, which slowly diffuse out of the resin beads into the treated water and thus interfere with its quality during the early part of the service run. Each column is first rinsed until the conductivity of the rinse water decreases to a value equal to or less than that of the feedwater. The rinse water is recycled through the two columns in series in a closed circuit, so that each resin removes the last traces of regenerant from the other. The amount of rinse water used is reduced significantly and the quality of the treated water is improved.

Buffer Column. The final ion leakage at the output from the demineralization units consists of sodium hydroxide and silica (see Section 7.4). The pH is slightly alkaline, normally between 7 and 9. If a neutral effluent is required, sodium

hydroxide leakage can be taken up by a cation-exchange material, the most efficient being a weakly acidic resin. This is known as a buffer column. Since the reaction is a pure neutralization, it is very fast and efficient. Because the resin operates in the H – Na cycle, the selected carboxylic resin may swell considerably in operation, and it must have excellent osmotic stability.

Mixed Beds. When beads of a cation- and an anion-exchange resin (R_C and R_A, respectively) are mixed intimately, the normal equilibrium for each resin is displaced:

$$R_C^-H^+ + Na^+Cl^- + R_A^+OH^- \longrightarrow R_C^-Na^+ + R_A^+Cl^- + H_2O$$

This reaction produces water. The exchange process is no longer reversible and continues until completion. Mixed-bed resins in well-designed equipment reduce the concentration of dissolved salts to 0.01 mg/L, giving a conductivity of 0.055 µS/cm at 25 °C, equal to that of completely pure water. Regeneration is carried out after the two resins have been separated (see Section 10.2.4). The advantages of mixed beds are twofold: (1) they produce water of excellent quality in a single stage, and (2) final rinsing is very rapid because the regenerants neutralize each other. However, the operating capacities of the resins are quite low, and the end of the cycle (breakthrough) is very abrupt.

If the ionic concentration of the feedwater is low (i.e., for polishing), the limiting factor is the specific flow rate. Ordinary gel-type resins are used up to about 40 BV/h and macroporous resins up to 100 – 130 BV/h. The amounts of regenerant used are on the order of 100 g of acid per liter of cation-exchange resin and 100 g of sodium hydroxide per liter of anion-exchange resin. The ratios of resin volumes used ($R_AOH : R_CH$) vary between 2 : 1 and 1 : 1. If the feedwater contains neutral salts, the 2 : 1 ratio is chosen; if only traces of sodium hydroxide from the demineralization train are present, the 1 : 1 ratio is selected.

In mixed beds for general use where the feedwater has a high ionic concentration, each of the exchange resins is calculated as if it were in a separate bed. The capacities are multiplied by a reduction factor of about 0.8 to allow for imperfect regeneration caused by the resin mixing zone after backwash and separation, as well as by the mutual diluting effect of the resins.

Continuous Systems. In continuous systems (always used with counterflow regeneration), the exhausted resin layers are extracted continuously or, more frequently, semicontinuously at intervals of a few minutes. They are replaced by freshly regenerated resin introduced at the point where the treated liquid emerges from the column. The total volume of resin is reduced by rapid circulation. In large industrial demineralization plants, a constant supply of treated water is often required. With fixed-bed systems, this necessitates two alternately operating lines or a large treated-water tank to secure water supply during regeneration period. With continuous systems, a single unit can be used, which ensures that the quality of the treated liquid is virtually constant.

The plant must be completely automated. The main disadvantage of these systems lies in the complexity of their construction. Examples are described in Chapter 10.

9. Ion-Exchange Resin Combinations

Many combinations of ion-exchange units are employed in water treatment; only the most widely used are considered here and summarized in Figure 27. They include pretreatment, softening, demineralization (primary system), and polishing. Softening exchanges Ca^{2+} and Mg^{2+} for Na^+ ions, whereas demineralization exchanges all cations for H^+ and all anions for OH^- ions. Polishing removes the cations and anions that have "escaped" the first-stage demineralization.

9.1. Pretreatment

Before being allowed to percolate through an ion-exchange column, the solution to be treated must be thoroughly filtered to free it from suspended matter. Organic matter can also be partly removed by flocculation, by using ferric chloride or aluminum sulfate with the possible addition of polyelectrolytes.

When the raw water is highly alkaline, the classical process of lime softening may be used to remove alkaline salts as calcium carbonate.

Figure 27. Combination ion-exchange systems for water treatment
DG = atmospheric degasser; IN = inert resin; SAC = strongly acidic cation exchanger; SBA = strongly basic anion exchanger; WAC = weakly acidic cation exchanger; WBA = weakly basic anion exchanger

This process, known as de-alkalization or carbonate removal, reduces the ionic load on subsequent ion-exchange units.

9.2. Softening

Pretreatment can be followed by softening (Figure 27, route a) with a single strongly acidic cation-exchange resin regenerated with sodium chloride.

Carbonate removal can also be combined with softening (Fig. 27, route b) to reduce the salinity of hard alkaline water and remove the hardness for use in low-pressure boilers and as cooling water. The pH may have to be increased from 4.5 to ca. 8 with sodium hydroxide.

9.3. Demineralization (Primary System)

The abbreviations used in this section are defined in Figure 27.

Degasser. As soon as the alkalinity of the raw water exceeds ca. 1 meq/L, an atmospheric degasser (DG) should be used in the system. When the solution flows through the cation-exchange resin, bicarbonate ions (and carbonate ions if any) are converted into carbon dioxide, which is removed in the degasser instead of passing to the strongly basic resin and being taken up there. A degasser is assumed to be present in all systems except those with mixed beds. The cation-free water at the degasser outlet contains 0.2–0.3 meq of free carbon dioxide per liter.

SAC – WBA – DG System (Fig. 27, route c). If the raw water is hard, the SAC – WBA – DG system produces water with < 5 mg of dissolved salts per liter, together with silica and ca. 15 mg of carbon dioxide per liter. If the raw water is soft, however, sodium leakage can be quite high unless the SAC is regenerated by a counterflow system. This type of arrangement is used to produce water for medium-pressure boilers and for chemical processes. The degasser may be placed after the weakly basic anion-exchange unit to obtain maximum capacity from the resin (see Section 7.4).

SAC – DG – SBA System (Fig. 27, route d). This simple system produces very pure water suitable for most applications. The water quality obtained depends on the regeneration system and the amount of regenerant. With coflow regeneration, a conductivity of 5 – 25 µS/cm and a residual silica content of 50 – 200 µg/L can be achieved, depending on the quality of raw water. With counterflow regeneration, the corresponding values can reach 1 µS/cm and 5 – 25 µg of silica per liter. Small plants are often built without a degasser.

General-Purpose Mixed Bed (SAC+SBA). A working mixed bed system (Fig. 27, route e) produces very pure water (0.1 – 1 µS/cm; 10 – 100 µg of SiO_2 per liter), but its regeneration efficiency is moderate because it is impossible to fit a degasser. The system is therefore restricted to small laboratory units or water with very low salinity.

SAC – WBA – DG – SBA System (Fig. 27, route f). This system produces the same quality of water as the SAC – DG – SBA system (route d). Its advantage lies in the higher regeneration efficiency due to the weakly basic resin. The anion exchangers are regenerated in series in the direction from SBA to WBA, so that an excess of clean caustic soda passes through the final resin, usually in sufficient amounts to regenerate the weak resin.

WAC – SAC – WBA – DG – SBA System (Fig. 27, route g). A weakly acidic cation resin can be used in all the above systems for appropriate types of raw water (i.e., high alkalinity and even greater total hardness; see Section 7.4).

The system considered here should be used for large plants dealing with highly saline water in order to use the high efficiency of the WAC and WBA resins to reduce the cost of regeneration. Acid regeneration is carried out in the direction from SAC to WAC, and sodium hydroxide flows from SBA to WBA as in route f.

Layered Beds. Weakly and strongly acidic resins can be superposed in the same column, because a carboxylic resin is less dense than a sulfonic resin. In addition, fine particle size is used for the WAC and coarse particle size for

the SAC so that the two layers are still well-separated after the backwash. The same applies to anion exchangers. Ion-exchange units containing superposed weakly and strongly active resins are called layered or stratified beds.

These dual resin systems (Fig. 27, routes h – j) have a high efficiency only if counterflow regeneration is used. They then produce water of excellent quality (1 µS/cm, 5 – 20 µg of SiO_2 per liter) with low regenerant consumption (regeneration efficiencies close to 100 %) – all in a plant with only two exchange columns. Calculation of the capacities and maximization of the performance of the system are complex operations, but they can be carried out rapidly on a suitably programmed computer.

A difficulty can occur with some weakly basic anion-exchange resins when the difference between their density and that of their strongly basic partner is too small (polyacrylic resins). A solution to this problem is to use a high-density resin as the strongly basic exchanger (see Section 3.4).

9.4. Polishing

To remove the last traces of salts, a polishing unit can be installed after the primary demineralization system.

A final *buffer column* containing a carboxylic, or sometimes a sulfonic, exchanger (Fig. 27, route k) can remove sodium leakage from an anion-exchange resin (see Section 8.2, buffer column).

Two-column polishing (Fig. 27, route l) was often used before counterflow regeneration became widespread. The sodium and silica leakages were taken up by a strongly acidic and a strongly basic exchanger in series. Regeneration was carried out from SBA2 to SBA1 and from SAC2 to SAC1, a primitive kind of counterflow system, often referred to as thoroughfare regeneration.

The mixed-bed polisher (Fig. 27, route m) is the most widely used polishing system, with its three-component variation (Fig. 27, route n; see also Section 10.2.4). With a mixed bed, a theoretical conductivity of pure water (0.055 µS/cm at 25 °C) can be achieved; ion and silica leakages are ca. 1 µg/L. Because the mixed-bed polishing system has to deal with only a low ionic load, it has a long service run, and is regenerated only every 5 – 10 cycles of the primary system. If the weak acid concentration in the raw water is low, the SAC – WBA – DG – MB system can be used and all the weak acids are then retained in the strongly basic resin of the mixed-bed polishing system.

9.5. Choice of Resin

General Selection Criteria. To ensure efficient operation of an ion-exchange installation, minimize running costs, and obtain a maximum resin lifetime, the resins must be selected carefully. Before individual resins are selected, the following questions should be answered:

1) Is the solution to be treated aggressive? Does it contain oxidants?
2) What is the operating temperature?
3) Is the flow velocity high or moderate?
4) Is the resin bed deep or shallow?
5) Is a high operating capacity required?
6) Is the expected leakage very low?
7) Are the cycles long or short?
8) Is the regenerant hot?
9) Is the regenerant very concentrated?
10) Are the resins used in a fixed, packed, or fluidized-bed unit or in a continuous system?
11) Are the resins used in stratified-bed or in mixed-bed units?
12) Does the regeneration process have a resin transfer step?
13) Is an effluent total organic carbon (TOC) strictly limited?
14) Is the application in the food-processing or nuclear industry?

The answers to these questions provide useful hints for resin selection:

1) In the presence of oxidants, a resin with a high degree of cross-linking should be used (see Section 3.3).
2) High operating temperature is critical for the choice of strongly basic resins: above 40 °C, only type 1 resins should be used (see Section 3.3).

3) For a high flow rate, physically stable resins and a relatively coarse particle size should be used.
4) With deep beds, coarse resins should be used to minimize the pressure drop.
5) If a high capacity is required, gel-type resins are preferred over macroporous types; type 2 or acrylic anion resins give a higher capacity than type 1. For condensate polishing applications, or for strongly basic resins placed downstream from a weakly basic resin, a high operating capacity is not of prime importance, but flow rate is a dominating factor.
6) For low leakage, resins with high cross-linking (i.e., high selectivity) associated with high regenerant dosage will give the lowest concentration of residuals.
7) Long cycles increase possible fouling risks and tend to compress resin beds and create large pressure drops; mechanically strong resins are thus advisable. Short cycles mean frequent osmotic shocks; in this case, macroporous resins are generally more stable.
8) For a hot regenerant, see item 2.
9) Concentrated regenerant also mean stronger osmotic shocks; see item 7.
10) Packed beds, fluidized beds, and continuous systems call for special particle sizes.
11) In stratified-bed or mixed-bed units, the particle size and density of the resins must be selected to obtain perfect resin separation after backwash.
12) Resin transfers result in mechanical stress: tough resins must be selected.
13) For low effluent TOC, special resin grades must be used that give rise to a minimum of leachables. On the other hand, if the influent solution contains organics, the anion resin must be capable of removing them reversibly so that it does not become fouled (see Section 7.3).
14) For food processing or nuclear waste treatment, special resin grades are prepared by major resin manufacturers to comply with applicable regulations or specifications.

Weakly Acidic Cation Exchangers. For water dealkalization or as a first unit in a series of demineralization steps, a high-capacity carboxylic resin should be selected. The osmotic stress for such a resin operating between the H^+ and the Ca^{2+} or Mg^{2+} forms is generally moderate, and most weakly acidic resins are mechanically very stable. In applications involving the Na^+ or NH_4^+ forms, however, osmotic stability is essential; the best choice is a resin with limited swelling and a macroporous structure.

Strongly Acidic Cation Exchangers. For softening or demineralization of water, gel-type cation-exchange resins are generally chosen. Sulfonic resins have a maximum capacity for a degree of cross-linking corresponding to 8 % DVB (Section 3.1). Gel resins with 6 % DVB can be used for water softening, and 10 % DVB resins for the production of highly pure water. Macroporous resins are restricted to special applications, continuous processes, and the treatment of condensates.

Weakly Basic Anion Exchangers. A wide variety of weakly basic anion exchangers are available with different matrices and porosities. The main types are as follows:

1) *Macroporous polystyrene resins* are the most widely used and the strongest, but the capacity of the standard grades is not very high. For high ionic loads and low flow rates, some manufacturers offer special grades with lower moisture and higher volume capacities.
2) Polyacrylic resins have a higher capacity and excellent resistance against organic fouling. They are, however, more expensive and sometimes difficult to rinse after regeneration.
3) *Phenol–formaldehyde resins* are generally restricted to special applications, but they have a strong adsorptive power for organic matter.

Figure 28 illustrates the comparative operating capacities of types 1 and 2. The capacity is plotted against an arbitrary factor $K*$ which takes into account the water salinity and the flow rate.

Figure 28. Operating capacities of weakly basic resin ($SO_4^{2-}:Cl^- = 1:1$)
a) Polystyrene resin; b) Polyacrylic resin $K^* = 10^4 \frac{[CO_2]^2}{(FMA)(FR)^2}$ where FMA is the free mineral acidity and FR is the flow rate in bed volumes per hour.

Strongly Basic Anion Exchangers. Like cation exchangers, strongly basic anion exchangers are gel-type resins which are widely used for water treatment because of their high capacity. Macroporous resins are restricted to continuous systems, condensate polishing and special applications.

A distinction is made between the following three types:

1) *Polystyrene resins type 1* are very strongly basic and therefore achieve extremely low silica leakage. They withstand high temperature quite well and can be regenerated with sodium hydroxide up to 50 °C. However, their regeneration efficiency is only moderate, so that their capacity is rather low and they are subject to irreversible fouling by organic matter.
2) *Polystyrene resins type 2* are slightly less basic and have a better regeneration efficiency and higher capacity (about 20 % higher than type 1). They become fouled less quickly but withstand high temperature less well (see Section 3.3). Their silica leakage is higher.
3) *Polyacrylic resins* combine some of the advantages of types 1 and 2 polystyrene resins: low silica leakage, good capacity, moderate regeneration efficiency, high physical stability, and good elution of organic matter adsorbed. However, they are 25 % more expensive than polystyrene resins and can withstand only moderately high temperature (≤ 35 °C). The partially quaternized acrylic resins described in Section 7.4 (strongly basic resins) have a particularly high capacity.

Figure 29 shows the basic operating capacity of the three types of resin for water with a 1 / 1 Cl^-/SO_4^{2-} ratio with coflow regeneration. Figure 30 indicates the regenerability of the resins.

Figure 30. Regenerability of strongly basic anion exchangers
a) Polystyrene resin type 1; b) Polyacrylic resin; c) Polystyrene resin type 2

One or Two Anion Resins? Most water to be demineralized contains salts of both strong and weak acids, the former frequently in high proportion. The economic advantage of using weakly and strongly basic anion-exchange resins in series, due to considerable savings in caustic regenerant, is demonstrated in Section 9.3.

For small and medium-sized plants (up to ca. 40 m^3/h), capital cost considerations are generally predominant, so that a series of the type SAC – DG – SBA is often selected. Because of its relatively good regeneration efficiency, a type 2 polystyrene resin is a good candidate for the anion exchanger.

Dual base acrylic resins (see Section 7.4) offer an even higher operating capacity (0.8 to >1 eq/L) with low regenerant consumption if the influent water contains less than 5 % silica. The regenerant usage is 140 % of the capacity in reverse flow regeneration, and 150 – 190 % in coflow, depending on water composition.

Layered-bed systems are used for bigger plants. In very large installations, however (>100 m^3/h), hydraulic considerations often call for separate weak base and strongly basic resin columns. The strongly basic resin is generally a type 1 or an acrylic resin with a strong base functionality.

10. Plant Design

For a detailed discussion, see [66].

10.1. General Considerations

The size of the water treatment plant, number of columns, choice of resins, and type and amount of regenerant are largely determined by

1) The rate at which treated water is required
2) The specified quality of treated water
3) The capital cost of the plant
4) The running costs of the plant

Small, mass-produced ion-exchange plants generally use large amounts of regenerant to maximize water quality and operating capacity. Running costs are high, but the user benefits from low capital cost and operational simplicity.

Where very large volumes of water are required (e.g., plants for municipal softening and nitrate removal or in heavy industry), emphasis is placed on the reduction of running costs. A very high degree of removal is not required, and regenerant levels are kept as low as possible to raise the regeneration efficiency. Thus, large volumes of resin are required, which increases capital costs.

When treated water of ultrahigh quality is required in large quantities as feedwater for high-pressure boilers, high regenerant levels can be used, which result in high operating capacities, compact plants, and high running costs. However, reverse flow regenerated systems are now universally employed which have a lower regenerant dosage and hence improved regeneration efficiency. In water demineralization, the combined use of weak and strong electrolyte resins further improves the chemical efficiency of the system. A complete treatment cycle consists of four phases (Section 8.1):

1) Service, i.e., the phase during which the resin is exhausted
2) Decompaction of the bed by backwash
3) Regeneration
4) Rinsing

In units regenerated by reverse flow, decompaction is only carried out occasionally so as not to disturb the resin layers and lose the advantages associated with counterflow operation. Some systems provide for cleaning the upper layer each cycle by backwashing only the top 15 cm of the bed.

10.2. Fixed-Bed Ion-Exchange Units

10.2.1. Column Diameter

Column diameters vary from a few centimeters (in laboratory units) to 5 m. Industrial units usually have diameters of 0.8 – 3.6 m. The depth of the resin bed also varies from 10 cm to about 3.5 m. For standard industrial units, bed depths should generally not be less than 70 cm. The maximum depth depends on the head loss that can be tolerated. Most units have resin beds from 1 to 2 m in depth. The main problem lies in producing even flow across the bed, because the liquid to be treated and the regenerant must be in

uniform contact with the whole volume of resin to allow stable horizontal wavefronts to develop and move vertically through the beds.

10.2.2. Small-Scale Units

Figure 31 shows a typical column designed for domestic water softening with a diameter up to about 50 cm. The outer cylinder is constructed from polyester reinforced with fiber glass. The water and regenerant inlet and the backwash outlet are combined in a single large strainer formed by a plastic cylinder with slits ca. 0.25 mm wide through which resin beads cannot pass. The treated water outlet is formed by a pipe concentric with the input strainer and fitted with a polyamide screen at the bottom. This type of unit is fully automatic; a multiport valve is fitted directly on top of the cylinder so as to form a compact arrangement with the system of inlet and outlet pipes.

Figure 31. Small-scale water softener
a) Control unit; b) Resin; c) Solid salt; d) Saturated brine

Small counterflow units, such as those normally used for domestic softeners, can be extremely simple, consisting of a column similar to that shown in Figure 31 but completely filled with resin. Although backwashing is not possible, the units operate satisfactorily because any dirt is filtered out at the top of the resin bed and washed out during reverse-flow regeneration.

10.2.3. Industrial Co- and Counterflow Plants

Industrial demineralization units are typically rubber-lined and fabricated from steel. A rubber layer about 3 mm thick is needed to protect the steel against acid corrosion. Various distribution and recycling systems are used to ensure even flow across the resin. Four examples are illustrated in Figure 32.

In coflow regenerated units, a regenerant distributor should be located just above the resin bed, as shown in Figure 32 A. In some simple columns, the regenerant is introduced at the top of the column. Regeneration is less efficient, as the regenerant is diluted before it reaches the resin. Because the columns are constantly filled with water during the whole cycle, space above the resin bed must be sufficient to allow for expansion of the bed during the backwash phase. When introduced at the same level as the upper surface, dilution is negligible. Uniformity of flow is controlled by the collection system at the bottom of the column rather than by the inlet.

In Figure 32 A, the collection system is buried in successive layers of gravel, or pieces of crushed flint (h, i) or anthracite from 2 to 10 mm in size; the coarser layers are at the bottom and the finer at the top. The collection system consists of a main header pipe onto which a set of perforated lateral pipes is welded or screwed, the whole system being supported by a base plate. The space between this plate and the convex bottom of the column is filled with concrete (m) for strength and rigidity. This long-established system is still used for softeners or simple demineralizers and gives an extremely uniform flow.

Figure 32 B shows a unit with counterflow (upflow) regeneration. The treated water collector (j) has lateral pipes fitted with small plastic filtering nozzles or strainers (two types of strainer are illustrated in Fig. 33). Slits in the strainers allow water to pass but retain the resins. This system may cause problems when water of the highest purity is required. To obtain uniform collection, the lateral pipes must be spaced at intervals of less than 15 cm and form a network at the bottom of the column. This network can retain traces of regenerant that subsequently leak into the treated water.

In large industrial units, the particles filtered out of the resin bed must be removed with a

backwash. Many systems are available to keep the bed compact during service and regeneration while allowing it to expand during an occasional backwash. A broad distinction can be made between designs with a large freeboard, in which a backwash can be carried out in the ion-exchange vessel itself, and packed-bed designs, in which the ion-exchange vessel is fully packed with resin, without a freeboard.

Buried collector systems, as shown in Figures 32 B and 32 C, are widely used in designs that have a freeboard. Figure 34 shows how they are operated. During the exhaustion phase (A), the solution to be treated flows from the top to the bottom of the unit; regeneration is carried out by introducing the regenerant at the bottom and extracting it through the collector (C); the resin bed is maintained in a compact state by a

current of water from the top of the column or by compressed air which leaves with the spent regenerant through the collector. This type of construction enables the upper resin layer to be backwashed from the collector without disturbing the lower layers (B).

Figure 33. Examples of strainers used for industrial water-softening plants
A) Simple plate strainer (Johnson); B) Double strainer for two-chamber floating beds (Kleemeier, Schewe & Co, Herford, Germany)

In a variation of this process, the buried collector is replaced by a number of downpipes with strainers at their ends (see Figure 32 B); these long, candle-shaped tubes penetrate the resin. This system restricts the water flow less and gives a more even collection. In both systems, the layer of resin above the collector does not take part in the ion-exchange process because it is not regenerated. Air-holddown systems use an inert polymer instead of this inactive resin layer, to protect the ion-exchange resin and prevent its drying out during regeneration.

A very frequent and efficient collection method for water treatment is shown in Figures 32 C and D. It consists of a flat base plate, perforated at 15 cm intervals, and fitted with screwed-on strainers leading into a lower chamber. This method of construction is, however, relatively expensive. Since the base plate is not supported by concrete, it must be either very thick or supported by small metal pillars to withstand operating pressure. Moreover, the space underneath must be lined with vulcanized rubber and be large enough to accommodate a worker to carry out this operation. Another method is to fit the cylinder with a coupling flange, which adds to the cost.

Packed-Bed Column. A packed bed column is shown in Figure 32 D: the resin is kept between two nozzle plates (k), and there is almost no freeboard. The particular design here is a floating bed unit (Amberpack) with upflow loading.

For the treatment of valuable solutions (see Chap. 12), special units with a flat bottom and a precisely engineered collection system are frequently used to minimize the void volume and

the risk of regenerant "hide-out", i.e., a dead zone from which spent regenerant is difficult to wash out during rinsing steps. Hide-out is usually due to poor hydraulic distribution (channeling) or to an imperfect collecting system.

Stratified Bed Units. In upflow regenerated columns using the air- or water-holddown technology, a combination of weakly and strongly active resins can be used in theform of a layered or stratified bed (Figure 35). Selected resin grades with a suitable particle size and density are required to prevent mixing of the layers.

Figure 35. Stratified-bed unit
a) Weakly acidic or weakly basic resin; b) Strongly acidic or strongly basic resin; c) Regenerant collector; d) Nozzle plate

Split-Flow System [32]. As shown in Figure 36, the split-flow system has a regenerant collector (b) that is buried below the bed surface at about one-third of the resin bed depth. The regenerant distributor (a) is located just above the bed surface. The regenerant is introduced simultaneously through the distributor and at the bottom of the column. The top stream keeps the bed compacted and regenerates the most exhausted part of the resin, whereas the bottom stream ensures that the lowest layers are always completely regenerated. This system also allows the upper part of the bed to be backwashed without disturbing the lower layers.

Figure 36. Split-flow system
a) Regenerant distributor; b) Regenerant collector; c) Resin; d) Nozzle plate

Econex System. In the Econex system of Davy Bamag (Fig. 37) [31], the upper part of the column is filled with inert material (b), which is used for compaction and can be removed to decompact the bed.

Floating-Bed Unit. The floating bed, invented and patented by Bayer in 1963 [27], is a reverse counterflow system (Fig. 38). During the service phase, the flow of water is from bottom to top, whereas the column is regenerated from top to bottom. The unit consists of a vessel fitted with an upper and a lower strainer rack. In practice, the vessel is filled almost completely with resin to prevent its becoming too fluid. A layer of light, inert, unbreakable resin granules may be used to prevent the fine particles or pieces of active resin from clogging the upper strainers. The unit is compact and has been quite successful, but has some limitations: it must operate at a minimum flow rate to prevent fluidization of the bed, and it is sensitive to the presence of suspended solids in the feed.

A variation of the floating bed has two chambers that are separated by a floor fitted with double strainers (d) and allows two resins to be placed in a single column (Fig. 39). The resins are regenerated in the direction from SAC to WAC or from SBA to WBA (see Section 9.3).

Figure 38. Floating-bed unit
a) Inert floating resin; b) Ion-exchange resin; c) Void space; d) Nozzle plate

Amberpack System. The Amberpack system of Rohm and Haas [28] is an improved floating-bed unit. It has one or two small ancillary backwash columns into which portions of the resin beds can be transferred for the removal of fines or suspended solids, as shown in Figure 40.

UFD System. In the UFD system of Degrémont (Fig. 41) [29], the resin fills the column completely (as in the floating bed), but percolation occurs in the conventional direction (downflow), and regeneration in the floating-bed mode (upflow).

UpCoRe System. This system, proposed by Esmil [30] and licensed to Dow Chemical under the name UpCoRe, is very similar to the UFD system. It is less sensitive to the presence of suspended solids than the floating-bed system. However, regeneration of the bed at a high flow rate makes it slightly less efficient.

Recoflo System. The Recoflo system is a shallow-bed process offered by Eco-Tec (Fig. 42) [33], using fine mesh resins (particle size 75 – 150 μm) between two distributing and collecting plates. The bed depth is usually 15 cm,

and the run length is typically only 5 – 30 min. Regeneration time is correspondingly short.

10.2.4. Mixed Beds

General Case. The mixed-bed principle was described in Section 8.2. Successful operation depends on the fact that the resins are separated by backwashing and settling before each component is regenerated. The densities of the resins normally used are 1.07 – 1.10 for the strongly basic resin and 1.20 – 1.30 for the strongly acidic resin. These are sufficiently different for the resin to be well-separated by backwashing, provided the cation exchanger does not contain too many fine particles or the anion exchanger too many large beads.

A typical mixed-bed design is shown in Figure 43. Untreated water enters at the top of the column through a strainer that also acts as the backwash outlet and prevents loss of resin. A sodium hydroxide distributor (c) is placed just above the bed top, and an intermediate central collector (d) is located at the interface between the two resins.

The operational cycle is illustrated in Figure 44 and consists of the following stages:

1) Service (Fig. 44 A)
2) Backwash for bed separation and subsequent settling (B)
3) Regeneration of the anion exchanger (C), followed by a rinse (the spent regenerant and rinse water leave via the central collector)
4) Regeneration of the cation exchanger with acid introduced through the bottom of the column and extracted through the central collector (D) followed by a rinse
5) Re-mixing of the resins with compressed air (E), followed by a final rinse

A small counterflow of water is advisable during the two regeneration stages to restrict the diffusion of acid into the anion exchanger and of sodium hydroxide into the cation exchanger. The two resin beds can also be regenerated simultaneously, with both spent regenerants leaving through the central collector. Although this system is very efficient, problems may arise due to precipitation of calcium carbonate or ferric hydroxide when the acid and the alkaline effluents meet. However, this situation is encountered mainly in general-purpose mixed beds and only rarely in polishing systems.

Three-Component Mixed Beds. Three-component mixed beds, known under the trade names Triobed (Duolite) or Ambersep (Rohm and Haas), overcome the problem of mixing of resins at the interface [34]. A layer of inert polymer beads, with a density intermediate between those of the cation- and anion-exchange resins, is mixed with both. Backwashing causes the mixture to split into three distinct layers, giving complete separation between the two ion exchangers (Fig. 45). This prevents cross-contamination, improves regeneration efficiency, and considerably reduces ionic leakage [35], [36].

However, the inert beads, being less hydrophilic than ion exchange resins, can cause operational problems. The availabilty of resins with uniform particle size and sophisticated regeneration technologies have gradually reduced the popularity of the Triobed concept.

External Regeneration. In the treatment of condensates or in polishing that follows a demineralizing system, the water to be treated by the mixed bed has a very low salinity. As a result, only a small exchange capacity is required and the units are therefore made as small as possible. They operate at very high specific flow rates of up to 130 BV/h. Any internal obstruction in the column can cause high pressure; therefore, these units are constructed as simply as possible (one rack of strainers, bed depths of ca. 1 m to avoid excessive head loss). To prevent accidental inlet of regenerant chemicals into the condensate circuit, the resins are transferred to separate regeneration units that operate at much lower flow rates. A single regeneration station can serve a series of mixed-bed units, as shown in Figure 46.

It may consist of several separate columns, specially designed to produce maximum separation of the resins and the best possible regeneration efficiency:

1) A separation column, also used for regenerating the cation exchanger
2) A column to which the anion exchanger is transferred for regeneration
3) A mixing and waiting column

An example of a mixed-bed unit as used for condensate polishing is shown in Figure 47.

10.2.5. Other Ion-Exchange Polishers

In the *Amberpack Sandwich polisher* of Rohm and Haas (Figure 48), a strongly acidic cation-exchange resin is combined with a strongly basic anion-exchange resin in two separate compartments of a column. The two compartments communicate via a plate fitted with double nozzles. A collecting device located just below the separation plate serves as a regenerant collector for the upper compartment and a regenerant distributor for the lower compartment.

In the *Tripol* process of Permutit-Boby [55], [68], three resins, (SAC1/SBA/SAC2) are placed in three shallow compartments of a single column. The second cation-exchange resin compartment, which is always very highly regenerated, acts as a final sodium trap.

The *Multistep* process of Bayer [56] is essentially the same as the Tripol process but operates in the opposite direction, in the floating-bed mode.

10.3. Continuously Circulated Ion-Exchange Resins [37]

As discussed in Section 8.2, automatic units in which the resin circulates continuously or intermittently should offer the following advantages:

- Smaller floor areas
- Smaller resin volume
- Continuous flow of regeneration liquids

In all resin-circulating units the resin flows counter to the solution to be treated. The exhaustion, regeneration, and rinsing stages occur simultaneously in different columns or in different sections of the same column.

The difficulties associated with circulation of the resin, its more rapid exhaustion than in fixed-bed units, and the complex construction of continuous systems have restricted their successful application. The counterflow processes described in Section 10.2.2 are much more widely used at present. However, mention should be made of some continuous processes that are still in operation:

1) The *Asahi process* [38], invented in Japan and finally developed in France by Degrémont (Fig. 49);
2) The *Kontimat process* [39] developed by Hager und Elsässer; and
3) The *Higgins process* of Chem-Seps [40].

Figure 50. External pipework and valves

10.4. External Valves and Pipework

A typical arrangement of external valves and pipework is shown in Figure 50. In the case of automatic softeners, separate valves can be replaced by a single multiport valve actuated by means of an electronic scheduler. For large systems, separate pneumatically or hydraulically controlled valves are used.

10.5. Control Systems

The quality of water produced by a plant must be monitored. As soon as it falls below a previously specified level, the service stage is stopped and the regeneration stage initiated. This section briefly describes the measuring instruments used in monitoring.

Timers. For domestic water softeners, daily consumption is assumed to be constant, and the softener is scaled to require regeneration at fixed intervals (e.g., once every three days). A timer initiates the process automatically, and regeneration frequency can be varied according to changing requirements. The method is simple and reliable, but wasteful, because regeneration is always initiated before the softener is exhausted.

Quantity Measurement. In communal buildings or laundries, where a cheaper and more flexible method is required, a contacting-head flow meter can be installed which automatically initiates regeneration as soon as a given volume of water has passed. This method is accurate as long as the hardness of the water supply does not vary.

Automatic Hardness Detector. A colorimetric hardness analyzer can be installed at the output of the softener to initiate regeneration when the allowed level of leakage is reached. This avoids waste of regenerant, but the analyzer is relatively expensive and the method is used chiefly in large industrial installations.

Conductivity Meters. Demineralizers are normally controlled by measuring electrical conductivity. Simple, reliable instruments can be installed to initiate regeneration when the conductivity of the treated water rises above a preset alarm value (e.g., 0.25 μS/cm for mixed-bed units or 10 μS/cm for two-bed units).

The breakthrough of silica, which has no detectable conductivity, can cause a problem. A common, reasonably reliable way of dealing with this is to place a conductivity probe above the bottom of the bed. The position of the probe is calculated in such a way that the wavefront of chlorides moving down the bed reaches the probe before the silica wavefront reaches the bottom. However, this method is not reliable enough to be used for high-pressure boiler water, in which the absence of silica is vital.

Silicometers are automatic colorimetric analyzers that operate like hardness detectors. They normally analyze water taken from a sampling point located above the bottom to ensure that no silica leaves the unit. They require very careful maintenance.

Differential Conductivity. For monitoring hydrogen-ion exchangers, a small separate cation-exchange column is set up and maintained in a highly regenerated condition by passing a large excess of acid through it at each regeneration of the main unit. During the service stage, a continuous sample of water from the main unit is passed through the test column and the difference in conductivity is monitored continuously. The difference is small and can stay constant or decrease during the run. A sudden increase marks the end of the cycle, indicating breakthrough from the main unit (see Section 6.3).

pH Measurement [67]. Although pH is easily measured, it is not a very useful parameter for plant control because unbuffered demineralized water tends to give variable values. Furthermore, the change in pH at the end of the cycle is less distinct and more subject to random changes than the variation in conductivity.

Sodium Electrodes. For cation exchangers, sodium-sensitive electrodes afford an extremely sensitive and accurate method of control.

11. Special Processes in Water Treatment

This chapter deals with special ion-exchange processes used in water treatment applications.

11.1. Removal of Organic Matter

In certain water with low salt concentrations, the fouling factor N (see Section 7.3) may become very high. To protect the anion-exchange resins in a demineralization plant, a special resin column can be installed at the head of the system to trap the organic matter. These resins are known as *organic scavengers.* Two kinds are available:

1) Highly porous strongly basic polystyrene or polyacrylic resins used in the chloride form for neutral or alkaline water, and regenerated with a mixture of sodium chloride and sodium hydroxide (e.g., Amberlite IRA900, Amberlite IRA958)
2) Weakly basic phenol – formaldehyde resin (e.g., Duolite A7) for water with high sulfate concentration, regenerated with sodium hydroxide (this resin is also capable of retaining certain detergents).

These scavenger resins have a limited efficiency, and their popularity decreased after the development of acrylic anion resins, which have excellent resistance to organic fouling. Furthermore, ultrafiltration is often superior for removing organic matter from water.

11.2. Treatment of Potable Water

Ion-exchange resins do not transform chemically or bacteriologically contaminated water into drinking water. Other processes are necessary, such as coagulation, filtration, chlorination, or ozonization. However, ion exchange can be used to reduce or remove excess hardness, alkalinity, nitrate or sulfate content, heavy metals, or radioactive substances from water destined for human or animal consumption. Dealkalization with carboxylic resins is frequently used in northern European breweries to prepare water that will make good beer. Many private houses, apartment buildings, or small communities have water softeners for domestic use.

Most ion-exchange resins, although totally insoluble, release minute amounts of residual organic raw materials into the treated water, particularly when they are new [41]. These impurities may not be allowed if the treated water (or solution in food-processing applications) is to be consumed by humans. Several countries now have regulations that must be observed by suppliers of potable water treatment equipment, including ion-exchange resins. In the United States [42], France [43], and Germany [44], these regulations specify the amount of impurities that may be released by the resin into the water. The composition of authorized resins is also described.

Removal of Nitrates [45]. In Europe and the United States, a trend toward higher nitrate concentration has been observed in both surface and groundwater. Nitrate levels higher than 50 mg/L endanger children's health. Any strongly basic resin in chloride form can remove nitrate from water. Unfortunately, the efficiency of standard strongly basic resins is only moderate because these resins also absorb sulfate and some bicarbonate, both of which are present in higher concentration than nitrate. This represents a waste of capacity and regenerant, and causes large variations in the quality of the treated water with regard to its sulfate (almost completely removed), bicarbonate (reduced), and chloride (increased) concentrations. These disadvantages can be partly alleviated by regenerating the resin with a mixture of sodium chloride, sulfate, and bicarbonate to reduce the variations in water quality [46].

Resins with a higher affinity for nitrates than for sulfates were developed in 1985 (Imac HP 555). They offer an advantage over conventional strongly basic resins when the water to be purified contains a high proportion of sulfate.

Carix Process. This was developed in Germany by the Kernforschungszentrum (Nuclear Research Center) in Karlsruhe [47]. It is unique in that it allows partial demineralization of water using carbonic acid ($CO_2 + H_2O$) as the sole regenerant. The salinity of the environment is not increased as is the case when a mineral acid and sodium hydroxide are used for regeneration. Moreover, in a mixed bed, the cation and anion resins do not require separation for regeneration, and the carbonic acid produced during service can be recovered and pressurized for use in the next regeneration sequence.

Two special acrylic resins are the key to the process: a weakly acidic cation exchanger (Amberlite IRC50) and a strongly basic anion exchanger (Amberlite IRA458). At the beginning of the service run, the cation resin is in its carboxylic acid form, whereas the anion resin is in the bicarbonate form. The principle of the Carix process can be described by the following reactions:

$$2R_A^+HCO_3^- + Ca^{2+}SO_4^{2-} \rightleftharpoons (R_A^+)_2SO_4^{2-} + Ca^{2+}(HCO_3^-)_2$$

$$2R_CCOO^-H^+ + Ca^{2+}(HCO_3^-)_2 \rightleftharpoons (R_CCOO^-)_2Ca^{2+} + 2CO_2 + 2H_2O$$

The combined mechanism of both resins produces the demineralization effect. The weakly acidic resin can exchange cations only if the water is alkaline. The alkalinity is produced by the anion resin, which is converted from the bicarbonate to the sulfate, nitrate, or chloride form.

Regeneration is carried out by a mechanism in exactly the opposite order. High carbon dioxide pressure displaces the second equation to the left; bicarbonate salts are formed in relatively high concentration and regenerate the anion resin.

Figure 51. Carix process – profile of treated water in a partial demineralization test aimed at softening water
Cation : anion resin volume ratio = 2 : 1. Dashed lines indicate concentrations in raw water. Solid lines indicate concentrations in product water

Being reversible, the reactions are never complete, but the Carix process results in a 40 – 50 % reduction of raw water salinity. The system is particularly effective for reducing the concentration of hardness, bicarbonate, sulfate, and nitrate. Typical breakthrough curves are shown as a function of time in Figure 51. A schematic diagram of the first full-scale Carix installation is illustrated in Figure 52. The Carix process is not limited to the treatment of potable water. It is very economical in terms of regenerant usage and very environment-friendly. However, it brings about only a partial demineralization of water.

Disinfection of Water and Resins. Normal ion-exchange resins do not sterilize water. Moreover, they may promote microbial growth during shutdown periods. If a solution contaminated with microorganisms flows steadily through a resin bed, most of the insoluble contaminants are filtered out on the resin surface. However, as soon as flow stops, the immobilized silt provides an ideal feedstock for incoming bacteria. The bacteria proliferate, contaminating the treated solution when service is resumed. Both the solution and the resin bed must therefore be disinfected.

Influent water can normally be disinfected with chlorine or ozone. Unfortunately, this may often not be sufficient, because these oxidants are almost totally consumed by the silt and debris deposited on the bed surface and by the resin itself. The *resin bed* must therefore also be disinfected. This can be done at regular intervals by using chemical bactericides such as chlorine, quaternary ammonium salts, or peracetic acid. Resin manufacturers provide some guidance in this respect.

Water softeners are frequently disinfected with chlorine produced by electrolysis of the brine used for regeneration. This is common practice in Germany, where all domestic softeners are equipped with an appropriate device. Another method involves mixing a small percentage (usually 1 – 3 %) of a special resin containing precipitated silver with the actual softening resin. The precious metal diffuses within the resin bed during standby period and prevents the growth of bacteria. Unfortunately, some strains become progressively resistant to silver.

Triiodide resins, which are strongly basic anion exchangers loaded with a large amount of the triiodide ion, can disinfect treated water. They are used in India and other tropical countries.

11.3. Treatment of Brackish Water

For many years, ion-exchange systems, such as those with SAC – WBA pairs (see Chap. 9), were used to demineralize brackish water containing up to 2500 mg (ca. 50 meq) of salt per liter. However, reverse osmosis has almost completely replaced ion exchange, which is now limited for economic reasons to water containing < 20 meq/L.

The Desal Process. Developed by Rohm and Haas in 1964 [48], the Desal system uses three columns: the first and third contain medium-basicity acrylic resins in the bicarbonate and hydroxide forms, respectively; the center column is filled with a carboxylic resin.

Exchange reactions for the three columns are:

$$R_A^+HCO_3^- + Na^+Cl^- \longrightarrow R_A^+Cl^- + Na^+HCO_3^-$$

$$R_C^-H^+ + Na^+HCO_3^- \longrightarrow R_C^-Na^+ + H_2O + CO_2$$

$$R_A^+OH^- + CO_2 \longrightarrow R_A^+HCO_3^-$$

During the process, the third column is converted to the bicarbonate form. Thus, after regeneration of the first column to the hydroxide form with a cheap alkali such as a calcium hydroxide suspension, and a normal regeneration of the cation unit with acid, the next cycle can proceed in the opposite direction, the third column now becoming the first.

This system has major limitations: sodium leakage from the center column is very high, so that desalination rarely exceeds 50 %. Bicarbonate is also lost from the system, unless the incoming water is strongly alkaline.

The Carbosoft Process. The softening of brackish water with a sulfonic acid resin in the sodium form is difficult if the influent contains a large proportion of sodium, due to its self-regenerating effect (see Section 7.2). Carboxylic

resins have a much better selectivity for multivalent ions than sulfonic resins. The Carbosoft process exploits this property. A weakly acidic resin in the sodium form selectively removes Ca^{2+} and Mg^{2+} ions from highly saline water with high efficiency and acceptably low leakage:

$$2\,RCOO^-Na^+ + Ca^{2+}Cl_2^- \longrightarrow (RCOO^-)_2Ca^{2+} + 2\,Na^+Cl^-$$

This system requires a two-step regeneration because the carboxylic resin cannot be regenerated with brine. The first step uses an acid:

$$(RCOO^-)_2Ca^{2+} + 2\,H^+Cl^- \longrightarrow 2\,RCOO^-H^+ + Ca^{2+}Cl_2^-$$

The resin is converted to the sodium form in a second step with dilute alkali:

$$RCOO^-H^+ + Na_2^+CO_3^{2-} \longrightarrow 2\,RCOO^-Na^+ + CO_2 + H_2O$$

Resins for the Carbosoft process must be able to withstand frequent sodium – hydrogen osmotic shock. In practice, only highly stable macroporous resins can be used. This process is widely employed to soften water injected as steam into oil wells to enhance the recovery of oil.

11.4. Processes Involving Sea Water

Sea water typically contains 35 g of sodium chloride per liter (i.e., 0.6 eq/L) and other minerals in lower concentration. This makes industrial-scale desalination by ion exchange totally impractical: only one bed volume of sea water would exhaust the resins, and more than one bed volume of treated water is needed for regenerant dilution and resin rinse. Therefore sea water desalination is performed exclusively by membrane methods (reverse osmosis and electrodialysis) or distillation. However, ion-exchange resins are well-suited to treat sea water in special cases.

Survival Kits. Many armed forces and airlines equip their soldiers and aircraft with emergency cartridges containing fine ion-exchange materials and silver salts to produce a few liters of potable water for immediate survival.

Softening of Sea Water. Sea water evaporators are subject to scaling with calcium sulfate. The Carbosoft process (Section 11.3) can be used to soften sea water.

Sea Water as a Regenerant. Because sea water contains essentially sodium chloride, it can be used to regenerate softening resins. However, the sodium chloride concentration of sea water (ca. 3.5 %) is lower than the optimum regenerant concentration (10 %), and the presence of other mineral salts is detrimental to hardness leakage and operating capacity.

11.5. Treatment of Condensates

Returned condensate from modern high-pressure boiler – turbine – condenser systems is not of suitable quality for recycling as boiler feedwater. It contains erosion and corrosion products, mainly insoluble iron oxides with traces of soluble salts of copper and other metals, together with salts arising from pinhole leaks in the condenser system which cause the entry of cooling water.

The problem of condenser leakage is particularly serious in coastal power stations where condensers are cooled by sea water. Boiler and turbine manufacturers keep up with the advances in ion exchange and demand increasingly strict standards for the quality of feedwater used in their equipment. The acceptable limit for sodium and chloride content is often expressed in parts per trillion or nanograms per liter.

As long as condenser leaks are small, raw condensates contain only very low concentrations of dissolved and suspended minerals, often a few micrograms per liter. During startup periods or with serious condenser leakage, concentrations may rise to 1 – 5 mg/L. The condensate is sometimes conditioned with 0.1 – 2 mg/L of ammonia or several milligrams of morpholine or other amines to raise the pH and reduce corrosion.

Special problems are associated with the filtration and demineralization of such condensates, and abundant literature exists on the subject [51], [52]. The processes fall into two main categories: one uses standard resins and plants similar to those used for demineralization; the

Figure 53. Regeneration with interface isolation
MB: mixed-bed unit; CRT: cation regeneration tower; ART: anion regeneration tower; MSV: mixing and storage vessel; IIV: interface isolation vessel
1) Exhausted resin transfer to regeneration station; 2) Transfer of interface resin into CRT; 3) Backwash for separation; 4) Anion resin transfer to ART; 5) Transfer of mixed interface to IIV; 6) Cation resin regeneration with acid; 7) Anion resin regeneration with caustic soda; 8) Cation resin transfer to MSV; 9) Anion resin transfer to MSV; 10) Air or nitrogen mixing of resins; 11) Return of mixed resins to mixed bed unit

other employs finely ground resins applied to precoated filters (see Section 11.5.2).

11.5.1. Conventional Resins

In the majority of plants, conventional resins in bead form are used in mixed beds (Section 10.2.4) which often operate with very high specific flow rates (100 – 130 BV/h) and very long cycles. For condensates conditioned with ammonia, the mixed bed is sometimes preceded by a cation exchanger which removes ammonia so that the mixed bed does not become saturated too quickly and can work at neutral pH where it is more efficient.

To ensure that ionic leakage is kept very low, especially at high pH,special techniques are available for the regeneration of mixed beds, mainly with a view to limiting cross-contamination between resins. Such processes include the following:

1) The *Seprex process* of Graver [53], in which the resins are separated by density differences in ca. 15 wt % sodium hydroxide solution.
2) The *Ammonex process* of Cochrane [54], in which an ammonia solution is circulated after regeneration of the anion exchanger to displace sodium from the contaminating cation resin.

Figure 54. Candle filter
a) Filter candle covered with resin precoat; b) Emptying outlet for upper compartment; c) Candle outlet

3) The *Conesep process* of Kennicott, where separation is greatly improved with a conical column and monitored with a conductivity device.
4) The Interface Isolation technique, shown in Figure 53, makes sure that the resin that cannot be completely separated and thus fully regenerated is not returned to the mixed bed unit.

11.5.2. Powdered Resins

The process launched by Graver under the name *Powdex* [57], [69] uses completely regenerated ion-exchange resins that are ground into a powder with particle sizes between 20 and 200 µm. The cation-exchange powder in H^+ form (sometimes NH_4^+ form) and the anion-exchange powder in OH^- form are mixed with water to yield a large flaky mass which is applied to candle columns (Fig. 54) or plate columns (Fig. 55). About 1 kg dry weight of mixed exchanger is used per square meter of filter surface. Several manufacturers of powdered resins have devised ready-made mixtures that are easier to use [58].

Figure 55. Plate filter
a) Distribution crown; b) Plate covered with resin cake

The advantage of powdered resins is that they filter suspended matter from the condensate very efficiently. Moreover, if radioactive substances are absorbed (e.g., in boiling water nuclear reactors, see Section 11.6), subsequent storage is easier because they are attached to a solid. The major disadvantage of powdered resins is their low demineralization capacity when condenser leakage is considerable.

Powdered resins are never regenerated. The caked layer of used resin is removed by a stream of compressed air, and a new layer is coated onto the surface. The criterion used to judge the end point is the head loss produced by compaction of the filtering layer from the effect of flow rate and the filtered matter: this head loss is normally limited to 180 kPa. In the case of condenser leakage, the end point occurs through exhaustion of the resin, whose operating exchange capacity is about 2 eq per kilogram of dry anion exchanger.

11.6. Water Treatment in the Nuclear Industry

In nuclear power plants, special problems occur because water circuits may contain radioactive elements. Water suspected of containing such products cannot be rejected to the public sewage system before being decontaminated. Similarly, spent regenerants of ion-exchange resins used in such circuits cannot be rejected either. Therefore, many nuclear circuits are treated with resins on a once-through basis: once exhausted, these resins are disposed of as nuclear waste (i.e., enclosed in cement, plastic, or glass as solid blocks; put in drums; and stored in underground nuclear dumps). Nuclear-grade resins must meet very strict purity specifications and are supplied in a highly regenerated form.

11.7. Production of Ultrapure Water [70]

In the semiconductor industry, the chips used for integrated circuits are washed with demineralized water and dried. Any mineral or organic impurity in the water may form a "bridge" between adjacent conductors which are separated by a fraction of a micrometer. This causes a short circuit and makes the part unusable. Therefore, extremely pure water must be used in this process. Typical water quality specifications are

Resistivity	18.2 MΩ · cm at 25 °C
(Conductivity	< 0.55 µS/cm at 25 °C)
TOC	< 3 µg/L
Microorganisms	< 2/mL
Suspended solids (< 1 µm)	< 10/mL

The production of such water requires the combination of several technologies, typically filtration, reverse osmosis, treatment with activated carbon, primary ion exchange, UV sterilization, microfiltration, final ion exchange, and ultrafiltration. Not only should the plant remove all impurities from the feedwater, but also none of its components must add any additional impurities to the treated water. Therefore, special materials with near-absolute insolubility must be used. The primary ion-exchange step often consists of two mixed-bed units in series. At the time of commissioning new resins, these are thoroughly cleaned by cycling.

In the final ion-exchange step, special resin grades of ultimate purity are used in nonregenerable "point-of-use" cartridges. These so-called semiconductor-grade resins are available from several producers and must comply with very strict specifications:

1) Extremely low content of leachable substances
2) Degree of regeneration close to 100 %
3) Absence of small resin fragments
4) Quick start-up rinse to specified resistivity and TOC value

12. Special Applications of Ion Exchange

Ever since their discovery, ion-exchange resins have been used primarily for water treatment. In 2000, 65 – 70 % of the resins produced were used for the softening or demineralization of water. The properties of ion-exchange resins were soon discovered to be advantageous in many areas other than water treatment. Since the end of the 1940s, resins have been used to treat sugar syrup or to extract precious metals. The number of such "special" applications has been constantly increasing because ion-exchange resins provide an efficient and elegant method for solving a large number of problems in chemical engineering. In many purification processes, the principles involved are similar to those described in previous chapters concerned with water treatment. However, specific properties of the solutions to be treated will affect the selection of resins: the feed solutions are often hot, colored, or viscous. Consequently, particle size distribution of the resin is adjusted to give acceptable pressure drops, and the porosity of the polymer is designed to prevent resin fouling or enhance the removal of color bodies or other large molecules from solution. Resins with uniform particle size (see Section 3.5) which have always been required for some applications, such as chromatographic separation, are now routinely available and have improved the efficiency of many processes.

Additionally, regulations now govern the use of ion exchange resins in many applications, particularly in the food processing industry. Many resins are authorized for the treatment of beverages and food, but regulations differ geographically.

There are also cases, such as catalysis, separation, or diffusion, where resins are used in a very different way, requiring specific columns and reactors. An exhaustive list of actual and potential applications cannot be given in this article. Table 9 lists in alphabetical order several uses of ion-exchange resins in the food, chemical, and pharmaceutical industries, and in hydrometallurgy. A few key examples are discussed in more detail. Some principal manufacturers of ion-exchange resins are listed in Table 11.

Table 11. Principal producers of ion-exchange resins

Company	Location	Principal trademarks
Bayer AG	Leverkusen, FRG	Lewatit
Dow Chemical Company	Midland, Michigan, USA	Dowex, Kastel
Mitsubishi Chemical	Tokyo, Japan	Diaion, Relite
Purolite Company	Bala Cynwyd, Pennsylvania, USA	Purolite
Rohm and Haas Company	Philadelphia, Pennsylvania, USA	Amberlite, Duolite, Imac
Sybron Corporation	Birmingham, New Jersey, USA	Ionac

12.1. Processing Steps

The uses of ion-exchange resins for various processing steps are described below. Resin manufacturers can provide more detailed information about specific processes and the corresponding ion exchange and adsorbent materials.

Table 9. Special uses of ion-exchange resins [a]

Product	Application[b]	Recommended resins [c], [d]
Acetic acid	Purification	Amberlite 252 – IRA67
Adipic acid	Catalyst recovery	Duolite C264NS H
Alkaloids	Separation & purification	Amberlite IR120, CR1320 K, IRC76, IRA402, IRA92
Alkylphenols	Catalysis	Amberlyst 15dry, 35dry, 36dry
Amino acids	Separation	Amberlite IRC50, 252, IRA67, IRA910, Duolite A7
Ammonium nitrate	Recovery & concentration	Duolite C264 – Amberlite IRA67
Anthocyanines	Recovery	Amberlite XAD16HP
Antibiotics	Purification (several processes)	Amberlite IRC50, XAD16HP, Amberjet 1500
Apple juice	Removal of hydroxymethylfurfural	Amberlite XAD16HP
Bisphenol A	Catalysis	Amberlyst 31wet
Borates	Removal from solution	Amberlite IRA743
Brine	Calcium, magnesium, strontium, barium removal	Duolite C467, Amberlite IRC748
Cadmium	Removal from waste	Duolite GT73, Amberlite IRC748
Caprolactam	Purification	Amberlite IRA402 – IR120
Carobs	Sugar recovery	Amberlite IR120 – IRA402
Casein	Precipitation	Amberlite 252
Catalysis (acidic)	Many processes	Amberlyst 15, 16, 31, 35, 36, 38
Cephalosporin	Extraction & purification	Amberlite IRA67, XAD1600
Chlorinated solvents	Removal from waste	Amberlite XAD4
Cholesterol	Drug for hypercholesterolhemia	Cholestyramine (Duolite AP143)
Chromates	Recovery from cooling circuits	Amberlite IRA96
Chromic acid	Iron removal	Amberlite 200C, Duolite C264NS
Chromic acid	Recovery & concentration	Amberlite 252 – IRA96, IRA92
Citric acid	Purification	Amberlite 252 – Duolite A561
Citrus juices	De-bittering	Amberlite XAD16HP
Cobalt	Recovery	Amberlite IRC76
Copper	Recovery & concentration	Amberlite IRC76, 252, IRC748, Duolite A7
Cyanides	Removal from waste	Amberlite IRA402, IRA958
Dates	Sugar recovery	Amberlite 252 – Duolite A561 – Amberlite IRA96
Electroplating	Rinse water recycling	Amberlite 252 – IRA96 – IRA410
Enzymes	Immobilization	Duolite A568, Amberlite IRA958
Esters	Esterification catalysis	Amberlyst 15wet, 36wet, Amberjet 1200 H
Formaldehyde	Acid removal	Amberlite IRA96, IRA92, IRA67
Fructose	Chromatographic separation	Amberlite CR1320 Ca
Fruit juices	Acid removal	Duolite A7, Amberlite IRA67
Fruit juices	Removal of fungicides	Amberlite XAD16HP
Gasoline	Octane enhancers (MTBE, ETBE, TAME)	Amberlyst 35wet, 15wet
Gelatin	Demineralization	Amberlite IR120 – IRA67, IRA92
Glucose	Demineralization	Amberlite 252 – IRA96, IRA92, IRA95
Glucose – fructose	Chromatographic separation	Amberlite CR1320 Ca
Glycerine	Demineralization & color removal	Amberlite IR120 – IRA96 – 200/IRA900
Glycol	Purification	Amberlite 252 – IRA96 – IRA900
Glyoxal	Nitrate removal	Amberlite IRA67
Gold	Recovery from plating solutions	Amberlite IRA410
Grape most	Rectification & sugar recovery	Amberlite SR1L – IRA92 – IRA900 – XAD16
Hydrochloric acid	Purification (iron and zinc removal)	Amberlite IRA402
Hydroculture	Resin as fertilizer	Lewatit HD5
Hydrogen peroxide	Purification	Amberlite XAD4, Amberlyst 15wet
Isomerase	Demineralization	Amberlite 252 – Duolite A561
Lactic acid	Demineralization	Imac HP1110 – Duolite A561
Lactose	Calcium removal	Imac HP336
Lactose	Demineralization	Imac HP1110 – Duolite A561
Lactose	Hydrolysis	Amberlyst 31wet
Lysine	Extraction & purification	Duolite C20N/2014

Table 9. (Continued)

Product	Application[b]	Recommended resins [c], [d]
Lysozyme	Recovery from egg white	Amberlite IRC50
Malic acid	Recovery from apple juice	Duolite A7
Mercury	Recovery or removal from waste	Duolite GT73
Methanol	Ammonia & sodium removal	Amberlite 252
Milk	Sodium removal	Imac HP1110
Molasse	Betain recovery	Amberlite CR1320 K, CR1310K
Molasse	Sugar recovery	Amberlite CR1320 K
Monosodium glutamate	Purification	Duolite C20N/2014, Duolite A7
Nickel	Iron and cobalt removal	Amberjet 4400
Nickel	Lead removal	Amberlite IRA96
Nickel	Recovery from waste	Amberlite IRC748, Amberlyst 35wet
Oxygen	Removal of traces from water	Amberlyst ER206
Pentaerythritol	Catalysis	Amberlite IRA958, IRA900
Phenol	Acid removal from phenol	Duolite A561, Amberlyst A21
Phenol	Purification	Amberlyst 16wet
Phenol	Removal from waste	Amberlite XAD4
Phosphoric acid	Purification	Amberlite 200C, 252
Pickling baths	Regeneration (Fe & Zn removal)	Amberlite IRA402
Platinum	Recovery	Amberlite IRA96, IRA402
Polyols	Demineralization (sugar industry)	Amberlite 252H, Amberlite IRA95, Amberlite IRA92
Polyols	Separation (sugar industry)	Amberlite CR1320 Ca, Amberlite CR1310 Ca
Semiconductor chips	Final rinse	Amberlite UP6040
Silica gels	Removal of sodium	Amberlite IRC84SP, IR120
Silver	Recovery	Amberlite IRA402, IRA67
Silver	Recovery	Amberlite IRA67, IRA402
Sorbitol	Demineralization	Amberlite 252 – IRA96 – 252/IRA900 – IRC76
Streptomycin	Purification	Amberlite IRC50, IRA404
Sucrose	Hydrolysis into glucose & fructose	Amberlyst 31wet
Sugar	Alkalization	Amberlite IRA958, IRA900
Sugar	Calcium removal (Gryllus process)	Amberlite 252
Sugar	Calcium removal (NRS process)	Amberlite SR1L
Sugar	Color removal from cane sugar	Amberlite IRA958 – IRA900

Sugar	Quentin process	Imac C16NS
Sugar	Sucrose inversion	Amberlyst 31wet
Sugars	Chromatographic separation	Amberlite CR1320 Ca
Sweeteners	Final polishing (purification of traces)	Amberlite 252/IRA910, XAD16HP
Tartaric acid	Purification	Imac HP1110 – Duolite A561
Uranium	Mining (recovery from leach liquors)	Amberjet 4400, Amberlite IRA910U
Vanadium	Recovery	Duolite C264NS
Vitamins	Extraction	Amberlite XAD1180, XAD16, IRC50
Vitamins	Purification	Amberlite 252, IRA96
Whey	Calcium removal	Imac HP336
Whey	Demineralization	Imac HP336 – HP1110 – HP661
Xylitol	Purification	Amberlite IRA900
Zinc	Recovery	Amberlite IRA402, IRC748

[a] All listed applications are commercial [b] For food-processing applications, the prospective user must check whether the suggested resin meets local regulations [c] For other producers, see Table 10 [d] Dashes between resin names indicate that several resins are used in series; commas mean that several options are available

12.1.1. Purification

Ion exchange is used for the removal of impurities from an aqueous or organic solution. The term impurities covers here a large spectrum of chemical species.

Deacidification. A solution containing acids is passed through a strongly basic anion exchanger in OH^- form or a weakly basic exchanger in free base form, depending on whether all acids or only strong acids are to be removed.

Since this process is a neutralization reaction, the product of reaction with a strongly basic resin

is water, and with a weakly basic resin the acid is taken up as a whole, so that the solution is effectively purified:

$$RN(CH_3)_2 + H^+Cl^- \longrightarrow [RNH(CH_3)_2]^+Cl^- \text{ or } RN(CH_3)_2 \cdot HCl$$

Examples: Removal of formic acid from formaldehyde, deacidification of fruit juice, and removal of mineral acids from alcohols.

Demineralization. All cations and anions may be removed (*total demineralization*) or only some of them, generally the strongly dissociated ions (*partial demineralization*). This is achieved by passing a solution successively through a cation-exchange resin in H^+ form and an anion-exchange resin either in OH^- or free base form. Non-ionized substances in the solution are largely unaffected by this treatment. This type of demineralization is sometimes called deashing.
Examples: Treatment of sugar syrups, glucose, antibiotics, glycerin, cheese whey, alcohols, polyols (e.g., sorbitol), and glycols.

In a variation of this process, organic acids are purified by using strongly acidic and weakly basic resins. Inorganic salts are removed, whereas weakly dissociated organic acids are not taken up by the anion-exchange resins. If the organic acid has a pK value lower than that of the resin, it is taken up during the first part of the run but then displaced by the stronger mineral acids, so that losses of the valuable organic acid are negligible or minimal. As weakly basic resins with different structures and active groups have different pK values, proper choice of resin will greatly enhance separation.
Examples: Demineralization of citric and lactic acids.

Selective Removal of Impurities. Harmful ions must be removed, while other constituents of the solution are affected as little as possible. Various sorts of selective resins are available.
Examples: The commonest applications are

1) Selective removal of toxic metals from industrial effluents by using complexing (chelating) resins (see Section 2.2.3) such as Amberlite IRC748 for transition metals and

Duolite GT73 for mercury, cadmium and other heavy metals
2) Nitrate removal from drinking water by using the Cl^- or HCO_3^- form of anion-exchange resins (see Section 11.2)
3) Calcium removal from saturated brine with an aminophosphonic resin (e.g., Duolite C467) that can remove Ca^{2+} in a concentration of 10^{-4} g/L from brine containing $>10^2$ g/L of Na^+
4) Removal of borate from drinking water with a resin having glucamino groups (e.g., Amberlite IRA743)

Decolorizing. differs from selective removal in that it normally combines ion exchange with adsorption. Resins have partially replaced bone char or activated carbon for this application, as they are easier to handle and to regenerate. Decolorizing is applied mainly to solutions of sugar or other organic compounds. Examples of the color bodies to be removed from solution are sugar degradation products, flavonoids, polyphenols, melanoidins, tannins, and anthocyanines. Because impurities responsible for the color of these solutions are often acidic, the resins used are normally highly porous anion exchangers, sometimes in combination with carbon, inorganic adsorbents, or nonionic resins.
Examples:

1) Strongly basic polystyrene materials in chloride form, strongly basic polyacrylic materials in chloride form are used for color removal from cane sugar, and regenerated with a sodium chloride brine
2) Weakly basic or nonionic phenol – formaldehyde resins are used for citric or tartaric acid
3) Acrylic weakly basic resins simultaneously decolorize and deacidify antibiotics
4) Aromatic polymeric adsorbents are used for the removal of polyphenols or anthocyanines

Adsorption of Impurities. True adsorption is not strictly speaking an ion-exchange process. However, adsorbent resins are so similar to ion-exchange resins that the process can be mentioned here. The adsorbent materials used are macroporous polystyrene such as the Amberlite XAD series or phenol – formaldehyde resins without active groups.
Examples: Current applications include the removal of impurities from effluents containing phenol derivatives, pesticides, chlorinated solvents, or dyes. Macroporous phenol – formaldehyde resins have also been used in cigarette filters to remove tar, aldehydes, and heavy nitriles.

12.1.2. Ion Substitution

All ion-exchange processes are ion substitutions. However, a distinction should be made between processes that remove ions while producing water or a pure solution of nonionic substances and those that leave the total ion concentration unchanged, merely replacing an undesirable ion by an acceptable one.

Softening. The principle of softening is the same as that used in water treatment: Ca^{2+}, Mg^{2+}, and possibly Fe^{2+} and Mn^{2+}, are replaced by Na^+ ions.
Example: The most widespread application is in the beet sugar industry, where the crude juice containing a high concentration of calcium is softened to prevent scaling in the evaporators. Variations on the basic softening process have been developed to save regenerant and reduce waste. One of the most efficient is the NRS process, in which regeneration of the cation-exchange resin is carried out with a mixture of the concentrated softened juice and a little caustic soda, so that no additional salt is required and the process produces no waste.

Desodation is a kind of reverse softening: the sodium in a solution is replaced by calcium, magnesium, or potassium, and the cation resin used is regenerated by salts of one or more of the latter metals.
Examples: Sodium removal from milk (Na – Ca, Na – K exchange) and the Quentin process in sugar refining (Na – Mg, K – Mg exchange).

Production of Organic Acids and Salts. Organic acids can be prepared from their salts simply by passage through a cation-exchange resin in H^+ form. This process has an excellent yield and is used widely to manufacture modified, water-soluble ethylenediaminetetraacetic acids and some amino acids from their sodium

salts. Conversely, an organic acid can be converted into its salt. One organic salt can also be converted into another.
Example: In the pharmaceutical industry, cephalosporin C is converted into its potassium salt by passage through a cation-exchange resin in K^+ form.

12.1.3. Recovery and Concentration

In recovery and concentration, the principle is the same as in selective purification, but the aim is different. Here, the objective is to recover a valuable substance from solution, so that the stage during which elution from the resin takes place is particularly important. In most cases, the substance recovered from the dilute solution is simultaneously concentrated during the regeneration stage.
Examples:

1) Recovery of traces of precious metals, most often in the form of metal complexes, in the metal plating industry (jewelry) and silver recovery from photographic baths
2) Isolation of pharmaceutical compounds during the manufacturing process (extraction and purification)
3) Recovery of ammonium nitrate in fertilizer plants
4) Recovery of sugar and amino acids from molasses in sugar refining by ion exclusion
5) Recovery and recycling of water by demineralizing the rinse water from surface treatment plants
6) Recovery of uranium or gold in the mining industry

12.1.4. Separation

A special type of ion-exchange resin (with fine, uniform particles and an accurately defined moisture content) is used in columns several meters tall for various industrial separation methods that are similar to those in chromatography. This technique allows separation of a mixture of ions, an electrolyte from a nonelectrolyte, and a mixture of nonelectrolytes (see also → Process-Scale Chromatography; → Basic Principles of Chromatography).

For separations involving nonelectrolytes, a special type of ion-exchange resin with fine, uniform particles and an accurately defined moisture content is used in columns several meters tall. Cation exchange resins with a mean diameter of 250 to 350 µm and a uniformity coefficient of less than 1.1 are used in many processes, in the appropriate ionic form, usually Ca, K, or Na. In the pharmaceutical field, chromatographic separations are carried out with polymeric adsorbents of similarly uniform particle size.

As shown in Tables 4 and 5, ions can be arranged in order of their relative affinity for a resin. For a sulfonated polystyrene exchange material, the following monovalent ions are listed as examples in order of increasing affinity:

$$Li^+ < H^+ < Na^+ < NH_4^+ < K^+ < Rb^+ < Cu^+ < Ag^+$$

Separation by Displacement. A small amount of the mixture to be separated is passed through a column (e.g., a mixture containing K^+ and Cs^+ is passed through a resin in Na^+ form). The ions taken up are then displaced by means of another ion with a greater affinity (e.g., Ag^+). The emergent liquor is thus fractionated because the silver ions, in turn, displace the sodium, potassium, and cesium ions.

Separation by selective displacement is a variation of the last process. A small amount of the mixture to be separated (e.g., Li^+ and Cs^+) is passed through a column containing a resin in a form with intermediate affinity (e.g., NH_4^+). This is followed by a solution containing NH_4^+ which displaces only the lithium. Lithium is therefore completely separated from cesium. Cesium can then be displaced by silver (Fig. 56).

Figure 56. Separation of Li^+ and Cs^+ by selective displacement in a resin initially in NH_4^+ form

This technique is called displacement chromatography. It can be applied to the separation of amino acids which are taken up by an H^+ form of cation-exchange resin column and displaced with sodium hydroxide or ammonium hydroxide.

Separation by Elution. A column is prepared as above but, instead of ions being displaced by an ion with greater affinity than those taken up, they are now eluted with an ion of lower affinity. This is normally the ion with which the resin was initially loaded (e.g., H^+). The ions to be separated are displaced toward the bottom of the column by the eluant (HCl in the example shown in Fig. 57). The ions always emerge in order of their increasing affinity for the resin and are usually separated well.

Figure 57. Separation of Na^+, K^+, Rb^+, and Cs^+ in a solution by elution with 0.1 N HCl through a resin initially in H^+ form

Separation by Ion Exclusion. An electrolyte can be separated from an electrolyte in an ion-exchange column by a sorption process (Fig. 58). The ion with which the resin column is loaded is normally the same as one of those in the electrolyte to be separated. For instance, an aqueous solution of a mixture of sodium chloride and glycerol can be passed through a column containing a cation-exchange resin in Na^+ form. Cation exchange does not take place because the column and the solution contain the same cation. The Cl^- anion cannot penetrate the resin because it encounters the Donnan potential which guarantees electrical neutrality within the resin (see Section 6.1). The electrolyte is thus excluded from the resin. The nonelectrolyte, on the other hand, can penetrate the resin by means of adsorption until its concentration is the same inside the beads as outside. When this equilibrium state has been reached, pure water is passed down the column and drives out the electrolyte more quickly than the glycerol, which must diffuse out of the beads. This process of alternating input of the mixture and displacement by water is repeated without the need to regenerate the resin, and successive fractions containing pure glycerol are obtained.

Figure 58. Separation of an electrolyte from an organic product by ion exclusion
a) Electrolyte; b) Organic compound

Examples: An exclusion process is used industrially to recover sugar from sugar beet molasses [59]. Figure 59 shows the successive fractions obtained, alternately rich in sugar and nonsugars. The same process can be applied to the separation of strong and weak electrolytes (e.g., hydrochloric acid from organic acids).

Figure 59. Recovery of sugar from molasses by ion exclusion
a) Conductivity; b) Sugar concentration
Fractions: AB nonsugars (residual molasses); BC recycled; CD sugar produced; DA recycled

Chromatography of Nonelectrolytes. Another property of resins becomes evident during separation by ion exclusion: if different nonelectrolytes are present in solution, the process not only separates out the mineral salts but also the nonelectrolytes from each other because of their different rate of uptake and release by the resin.

Example: Separation of glucose from fructose is carried out commercially with fine bead sul-

fonic resins, generally in the calcium form [60]. A typical elution profile is shown in Figure 60.

Figure 60. Separation of glucose from fructose in high-fructose corn syrup
a) Glucose; b) Fructose; c) Oligosaccharides

Separation by Acid Retardation. Somewhat surprisingly, an acid can be separated from its salts by using a column containing a strongly basic anion-exchange resin of suitable porosity and particle size [61]. This occurs because, at high concentration, the acid crosses the Donnan potential barrier (Donnan invasion) and is taken up by the resin, whereas the salts are excluded from it. The acid is thus "retarded", and the salts are allowed through. Pure fractions can be obtained at the output by passing concentrated electrolyte solution and water alternately down the column.
Example: Acid retardation is now used industrially for purifying and recycling acids that have been used for metal pickling. An elution curve is shown in Figure 61.

Figure 61. Acid retardation by a strong anion resin

12.1.5. Diffusion

An ion-exchange resin already loaded with ions releases them slowly into a solution. This property is used in two special applications.

Hydroponics. (Soilless Cultivation). A resin loaded with fertilizing elements can be used for the hydroculture of plants instead of liquid fertilizers [62]. The elements are released gradually into the water as needed by the plant (Fig. 62).

Figure 62. Hydroculture
a) Hydroponic resin; b) Beads of blown clay; c) Water level; d) Inner perforated pot; e) Outer pot

Delayed-Action Drugs. Instead of administering a pure drug directly, it can be absorbed onto a suitable resin and taken in this form. The active substance is then released more slowly in the stomach.

12.1.6. Catalysis (→ Heterogeneous Catalysis and and Solid Catalysts, Chap. 3.1.5.)

Acid or Alkaline Catalysis [63]. Because standard ion-exchange resins are insoluble acids or bases, they can be used with advantage in many organic reactions where an acidic or basic catalyst is required. Special macroporous sulfonic resins are used, for example, in esterification (e.g., the production of butyl acetate), synthesis (e.g., of methyl *tert*-butyl ether), or the hydrolysis of sucrose to glucose and fructose.

Catalysis with ion-exchange resins has the following advantages over the use of sulfuric acid:

1) A higher local concentration of H^+ (or OH^-) ions
2) No corrosion
3) Possibility of use in continuous processes
4) Fewer secondary reactions
5) Easy separation from the reaction medium (by simple filtration)

Catalyst Carrier. Some resins can be loaded with a metallic catalyst (palladium, silver, nickel, etc.), which is otherwise difficult to use because of its high solubility.

Enzyme Immobilization. Some ion-exchange resins can be loaded with enzymes to enable enzymatic reactions to take place continuously. Glucoisomerase or β-galactosidase, for example, can be taken up by weakly basic phenol – formaldehyde resins (see also → Immobilized Biocatalysts).

12.1.7. Dehydration

Ion-exchange resins are strongly hydrophilic. When dried, they tend to take up their quota of swelling water. This property is exploited in the two following applications.

Drying of Gases or Solvents. Previously dried sulfonic resins can be used to lower the humidity of air, gases, or organic solvents. The resins take up their own weight of water.

Dehydration of Alcohols. The affinity for water is so great that sulfonic resins can be used to dehydrate alcohols, (e.g., in converting ethylene glycol into dioxane or cyclohexanol into cyclohexene.

12.1.8. Coalescence on Oleophilic Resins

An oleophilic resin can be obtained by loading a resin permanently with an organic substance consisting of long-chain molecules [64]. In practice, a sulfonic resin loaded with an organic cation is used (e.g., an aromatic quaternary ammonium ion):

or a pyridinium ion:

The cationic part of the oleophilic molecule is taken up almost irreversibly by the cation-exchange resin. An oleophilic resin bead of this type is illustrated in Figure 63.

Figure 63. Schematic representation of an oleophilic resin bead
a) Sulfonic resin bead; b) Ionic end of oleophilic molecule; c) Oleophilic end of molecule

Figure 64. Elf coalescing deoiler
a) Oil – water mixture; b) Oleophilic resin; c) Decanted oil; d) Level controller operating the oil outlet valve

Water containing oils or fats passes through a column containing an oleophilic resin. The oil particles are taken up by the resin beads in the form of microscopic droplets. The droplets coalesce and grow in size as more oil is taken up. Beyond a certain size, the drops become detached from the resin and are then decanted in the normal way. This process has been developed on

an industrial scale as the Elf – ANVAR process [65]. A typical coalescing deoiling unit is shown in Figure 64.

12.1.9. Liquid Ion Exchangers
(→ Liquid – Liquid Extraction)

Liquid ion exchangers are high molecular mass, water-insoluble acids and bases that are soluble in oil and in organic solvents. The compounds have a hydrophobic structure and an ionogenic group. They are usually phosphonic acids and amines substituted with long-chain ($C_8 - C_{24}$) aliphatic groups. They are used for liquid – liquid extraction of electrolytes from aqueous solutions.

An example of cation exchange is the following reaction with a polyalkyl phosphonic acid:

$$(R_3PO_4H)_{org} + M^+ \rightleftharpoons (R_3PO_4M)_{org} + H^+$$

An example of anion exchange is the following reaction with a polyalkylamine in salt form:

$$(R_3NHA)_{org} + B^- \rightleftharpoons (R_3NHB)_{org} + A^-$$

where M^+ represents a metal cation, A^- and B^- represent two different anions, R is an alkyl substituent, and the subscript org denotes the organic phase. Recovery of the extracted component from the organic phase does not require distillation as is often the case in processes based on solubility differences. Instead, the liquid exchanger is "stripped" in a second liquid – liquid extraction, similar to the regeneration of solid ion exchangers. The regenerant (stripping agent) is an acid, base, or salt in aqueous solution. In practice, the liquid ion exchanger is used as a solution in an organic solvent (frequently kerosene), with an organic : aqueous phase ratio of between 1 : 1 and 1 : 4. In the exchange process, both immiscible phases are thoroughly mixed mechanically in conventional liquid – liquid extraction equipment (mixer – settlers, centrifugal contactors, and pulsed and nonpulsed extraction columns).

The advantages of liquid ion exchangers are the relative simplicity of their production, the possibility to adjust their concentration in the organic phase according to the concentration of the aqueous solution, and the possibility of continuous countercurrent operation. Their main disadvantage is the inevitable losses of solvent and ion exchanger during the extraction process.

The main industrial application of liquid ion exchangers is hydrometallurgy. Large plants are in operation for the recovery of uranium from sulfuric acid leach liquors. The uranyl sulfate anion is extracted with a dialkylamine and subsequently stripped with sodium carbonate, resulting in a water-soluble uranyl carbonate complex which can be precipitated (e.g., by addition of sodium hydroxide) to produce a "yellow cake" of uranium oxide.

Examples: Amberlite LA-1 and LA-2 liquid anion exchangers Rohm and Haas, USA.

12.1.10. Ion-Exchange Membranes
(→ Membranes and Membrane Separations)

Ion-exchange membranes are materials with ion-exchange properties that can be used as a separation wall between two solutions. They show pronounced differences in permeability toward counterions, co-ions, and neutral molecules. The membranes are permselective. Cationic membranes are permeable to cations and impermeable to anions. Anionic membranes are permeable to anions and impermeable to cations.

Ion-exchange membranes are classified as hetero- or homogeneous:

Heterogeneous membranes are made of finely ground ion-exchange resin particles embedded in an inert porous binder [polyethylene, poly(vinyl chloride)] in the form of flat sheets. The resin is usually sulfonated polystyrene for cationic membranes and polystyrene with quaternary ammonium groups for anionic membranes. To increase dimensional stability, the mixture is often reinforced with a woven fabric.

In *homogeneous membranes* the ion-exchange groups are grafted directly to the membrane polymer structure. Their manufacture is similar to that of bead-form ion-exchange resins. They are somewhat less stable than heterogeneous membranes, but have a more uniform structure. In the absence of electric current, the membrane is slightly permeable to nonelectrolytes and impermeable to electrolytes because the Donnan potential prevents co-ions from passing through it. Furthermore, the principle of electroneutrality makes it impossible

for counterions to concentrate on one side of the membrane. When an electric potential is applied, however, cations are attracted by the cathode and anions by the anode. In the case of a cation-exchange membrane, only cations can wander through it.

An example of application is the *electrolysis of brine* using a cation-exchange membrane (chlor-alkali process) to produce chlorine and caustic soda (→ Chlorine, Chap. 7.). Sodium chloride and water are introduced into the anode chamber where oxidation of the chloride ions to chlorine takes place. Water in the cathode chamber is reduced to hydrogen and hydroxyl ions. Sodium ions wander through the cation-exchange membrane into the cathode compartment and combine with the hydroxyl ions to form sodium hydroxide. Another important example is *electrodialysis,* where both cation- and anion-exchange membranes are used for demineralization of water (Fig. 65). If all three chambers are filled with sodium chloride solution, sodium passes through the cation-exchange membrane and produces NaOH in the cathode chamber, chloride goes through the anion-exchange membrane and produces HCl and the central chamber is progressively demineralized.

Figure 65. Electrodialysis for demineralization of water

In industrial practice, a large number of alternating cation- and anion-exchange membranes are combined for demineralization of water, especially brackish or sea water. Electrodialysis is also used for the demineralization of cheese whey to recover valuable proteins and lactose.

Membrane electrodes operating according to the principle of permselectivity can be used for analytical purposes. Ion-specific membranes are now available for measuring.

Important ion-exchange membrane manufacturers are Asahi Chemical (Japan), Asahi Glass (Japan), Du Pont (USA), Ionics (USA), Rhône-Poulenc (France), Sybron (USA), and Tokuyama Soda (Japan).

12.2. Technical Considerations

For special applications in softening, purification, demineralization, or recovery, the plants are often similar to those used in water treatment. Counterflow regeneration is sometimes used to improve regeneration efficiency and reduce leakage. Continuous systems (see Section 10.3) can be employed, e.g., in the softening of sugar syrup or the treatment of rinse water in electroplating. However, many special applications require special operating conditions.

Flow Rates. Concentrated solutions must frequently be dealt with, which requires relatively large amounts of resin. The specific flow rate is often low: 0.2 – 20 BV/h instead of the 10 – 100 BV/h used in water treatment.

Regenerant Recycling. Regenerant consumption can be reduced by recycling. The tails, which are relatively uncontaminated, can be used at the head of the next regeneration stage.

Merry-go-round Systems. To increase the treatment capacity of a plant and improve the quality of the treated liquid, a so-called merry-go-round system can be used. This involves passing the solution through several identical columns in series (at least two, but usually more), so that the one at the head is exhausted as completely as possible. When this state of exhaustion is reached, the next column is placed at the head of the series, and the one just regenerated is used for polishing while the exhausted column is regenerated. The cycle shifts by one column as each column at the head of the chain is exhausted. In this way, the product is obtained in the most concentrated form possible (Fig. 66).

Sweetening Off and On. In most of the purification processes described in Section 12.1.1, the liquid to be treated must be removed from the resin before the latter is regenerated. This involves inserting a rinsing stage before regeneration, a stage generally known as *sweetening*

off because of its similarity to the treatment of sugar syrup. In the same way, after this stage and a rinse of the water from the exchangers, the water filling the column is replaced by the liquid to be treated, a stage known as *sweetening on*.

The complete cycle thus consists of sweetening on, the service stage, sweetening off, decompaction, regeneration (or elution), and rinsing. Decompaction is sometimes carried out prior to sweetening off, with the liquid to be treated.

Figure 66. Extraction of streptomycin with weakly acidic resins (three columns in series)

Multistage Regeneration. The resin must sometimes be regenerated in several steps. In the first step, the substances taken up in one ionic form are removed or recovered. In the next step, the resin is converted into another ionic form more suitable for the service stage.

In the selective uptake of metals, for example, a carboxylic or chelating resin (see Section 2.2.3) is often used in Na^+ form in order not to lower the pH of the solution to be treated. However, the resin must be regenerated with acid. The H^+ form must then be converted to the Na^+ form with sodium hydroxide:

Service:

$$2\,RCOONa + ZnSO_4 \longrightarrow (RCOO)_2Zn + Na_2SO_4$$

Regeneration:

$$(RCOO)_2Zn + H_2SO_4 \longrightarrow 2\,RCOOH + ZnSO_4$$

Conversion to Na^+ form:

$$RCOOH + NaOH \longrightarrow RCOONa + H_2O$$

Temperature Control. Some viscous liquids, particularly concentrated organic solutions (e.g., heavy sugar syrups), must be decolorized when hot (70 – 80 °C) so that they remain fluid and do not crystallize. Other liquids, such as light sugar syrups, must be demineralized when cool (12 °C) so that they are not hydrolyzed when they come in contact with the cation exchanger in H^+ form. Temperature control thus plays a major role in many applications.

Special Plants. Some applications require special types of plant, e.g.,

1) Very long columns up to 10 m tall for sugar chromatography
2) Columns in the shape of truncated cones widening at the top to enable resins to swell during service or regeneration
3) Fluidized-bed systems, sometimes using high-density resins to treat liquids containing suspended matter

Simulated moving beds (SMBs) are progressively replacing the tall columns of the first industrial plants. Whilst the old plants had to be operated in a sequential, discontinuous way, alternating the feed solution to be separated and an eluant, the new SMB technology allows the separation of two or more compounds in a quasi-continuous, stepwise manner: the columns (typically 30 of them) are arranged in a carousel. The major system of this type is called ISEP [71] and is provided by the U.S. company AST (Advanced Separation Technologies). The feed and elution solutions are connected to a stationary upper distributor fitted with typically 20 ports, and the raffinate and the extract are connected to a lower stationary connector fitted with the same number of ports. The columns themselves are mounted on a rotating frame. The carousel rotates continuously at a speed of 0.1 to 1.5 revolutions per hour, and the ports are thus successively connected to all columns. A simplified scheme is shown in Fig. 67 with only eight resin

columns and six inlet and outlet ports. Figure 68 shows the principle of operation in two dimensions.

Figure 67. ISEP carousel (simplified)
a) Rotating resin columns; b) Stationary inlet ports; c) Stationary outlet ports

Figure 68. ISEP: two-dimensional view

Simulated moving beds can be used for purification of fermentation broth, sugar syrup deashing, decolorization of various solutions, separation of metals and other applications.

Abstract

The article first evaluates the general features of iron and its naturally occurring oxides. The production processes from ores are described and the producer countries listed. Bedded deposits enriched in iron account for ca. nine-tenths of potential iron reserves. Benefication steps include crushing, concentration, flotation, and/or roasting. The blast furnace is the dominant type of equipment for the production of iron metal. Part of the heat needed for the production of iron is used to heat up the raw materials to be processed and part of it is required for endothermic chemical reactions. Carbon and hydrocarbon carriers, chiefly in the form of coke, are gasified to the primary reducing agents (CO, H_2) in blast furnaces. The use of fossil reducing agents in iron making is subject to careful re-evaluation, and development of new reduction techniques is expected. Gaseous reducing agents other than those formed in the reduction reactor itself are derived from natural gas, oil, or coal. It is quite likely that coal will come to play an increasingly important role as a source for production of reducing gas. Gas generation on the basis of nuclear energy is expected to remain economic for many years, although some effort is currently being directed toward the use of a plasma arc for converting carbon sources into reducing gas.

The world steel industry is the principal consumer of refractories. The refractory-unit consumption for steel production has constantly decreased over the last decades due to new steelmaking technologies. The trend towards high-performance refractories is ongoing due to increasingly severe process conditions. The refractory materials used for the blast-furnace process and the hot-metal transport are discussed.

Finally, the thermodynamic and kinetic principles of ore reduction are evaluated in detail. This will provide an understanding of the process technology as well as a critical evaluation of the process with respect to cost effectiveness, product quality, and efficient utilization of the reducing agents.

1. Properties

Physical Properties. The physical properties of iron are strongly dependent on its degree of purity. In the evaluation of physical property data from the literature it is, therefore, necessary to know and to take into account the amount and the nature of the impurities. The following distinctions are made:

technically pure iron, containing 99.5 – 99.9 % Fe;
pure iron, containing 99.9 – 99.99 % Fe;
high-purity iron, containing 99.99 % Fe.

Frequently used physical material constants are summarized in Tables 1 and 2. The majority of the data pertains to technically pure iron; however, some data valid for pure iron are also included. For cases where the required accuracy is particularly high the original reference should be consulted [1 – 6].

Table 1. Crystallographic, thermal and mechanical properties of technically pure iron

Crystal structures and lattice constant a	
α-Fe body centered cubic	a = 0.2866 nm (25 °C)
γ-Fe face centered cubic	a = 0.3647 nm (910 °C)
δ-Fe body centered cubic	a = 0.2932 nm (1400 °C)
Transition points and enthalpies	
Curie point	760 °C; ΔH = 2.76 kJ/mol
α-Fe ↔ γ-Fe	910 °C; ΔH = 0.92 kJ/mol
γ-Fe ↔ δ-Fe	1400 °C; ΔH = 1.17 kJ/mol
δ-Fe ↔ melt	1539 °C; ΔH = 15.28 kJ/mol
Melt ↔ vapor	2880 °C; ΔH = 340.4 kJ/mol
Standard entropy	27.2 J/mol K
Molar heats as a function of temperature	
α-Fe (273 < T < 1033)	C_p = 17.50 + 24.77 T J mol^{-1} K^{-1}
α-Fe (1033 < T < 1183)	C_p = 37.68 T J mol^{-1} K^{-1}
γ-Fe (1183 < T < 1673)	C_p = 7.70 + 19.51 T J mol^{-1} K^{-1}
δ-Fe (1973 < T < 1812)	C_p = 43.96 T J mol^{-1} K^{-1}
Fe_L (1812 < T < 1873)	C_p = 41.87 T J mol^{-1} K^{-1}
C_p (0 – 1500 °C)	0.681 J g^{-1} K^{-1}
Thermal conductivity at 100 °C	72.44 W m^{-1} K^{-1}
Density	
at 20 °C	7.87 g/cm^3
at 1550 °C (liquid)	7.08 g/cm^3
Coefficient of thermal expansion (0 – 800 °C)	14.5×10^{-6} K^{-1}
Mechanical properties (measured for normalized samples containing 0.005 % C, 0.005 % O_2 and 4 to 24 grains per mm^2)	
Brinell hardness	44 – 55 HB
Lower yield point	90 – 140 N/mm^2
Tensile strength	220 – 280 N/mm^2
Elongation at fracture (L_0= 5 d_0)	40 – 60 %
Modulus of elasticity	210×10^3 N/mm^2
Shear modulus	82×10^3 N/mm^2
Vapor pressure (1812 K < T < 3153 K); p (mbar): $\log p = -19710\, T^{-1}\ 1.27 \log T + 13.39$	
Surface tension (1550 °C)	1.78 N/m
Kinematic viscosity (approximately linear relationship between those points)	
at 1450 °C (undercooled liquid)	6.7 mPa s
at 1750 °C	4.4 mPa s

Chemical Properties [7, 8]. Iron [*7439-89-6*], Fe, atomic number 26, A_r 55.847, belongs to group 8 of the periodic table and to the first row of the transition elements. The electron configuration of the lowest energy state is characterized by $3d^6\ 4s^2$. Although the energies corresponding to the 3*d* and 4*s* orbital functions of the neutral atom are similar, the *d* orbital function is more stable than the *s* function whenever the atom acquires a charge. Thus, in ionic compounds and in complexes with non-π-bonding ligands iron acquires an oxidation state of 2 or higher. The highest possible oxidation state of 8 (the sum of the 4*s* and 3*d* electrons) on the other hand, is not observed.

The acid character of iron oxides increases with increasing oxidation state. The bond in iron halides is more covalent the higher the oxidation state of iron. Accordingly, the hydrolysis increases with increasing valency of iron.

At room temperature metallic iron is stable in dry air and in water which does not contain carbon dioxide and air. Although the equilibrium of the oxidation reaction of iron in air is shifted toward the formation of the oxide, the rate of the reaction is drastically decreased by the formation of a protective layer of iron oxide. In fact, the reaction is virtually entirely suppressed. The so-called passivation of iron by concentrated nitric acid and strong oxidizers, e.g., dichromate containing acids, is likewise caused by the formation of a protective oxide layer. Iron is not dissolved by these acids because of the formation of a dense oxide layer, although it is readily dissolved in dilute mineral acids in accordance with its position in the galvanic series (E_0 = − 0.409 V). Iron is dissolved by hot concentrated sodium hydroxide and precipitates as iron hydroxide, $Fe_2O_3 \cdot nH_2O$, in the presence of oxygen.

In the presence of air-containing water and moist air iron is transformed into iron (III) oxyhydrate (rust) (→ Corrosion). The layer that is formed on the iron during this process is not dense but flakes off, in contrast to the aforementioned oxide layer, and a fresh iron surface is therefore exposed to corrosion.

The oxides of iron (→ Pigments, Inorganic) are very important for the production of iron. There are three oxides of iron: hematite (Fe_2O_3), magnetite (Fe_3O_4), and

Table 2. Electrical and magnetic properties of technically pure iron

Temperature θ, °C	20	200	400	600	800	1000
Specific electrical resistivity ϱ, μ Ω cm	10	20	40	70	108	115

wustite ($Fe_{1-y}O$), with $y = 0.045 - 0.135$. The oxygen ions form an almost dense close-packed structures in all three of the oxides.

Hematite [*1309-37-1*], the oxide of trivalent iron, exhibits two commercially important modifications. The stable form, α-hematite, has the crystal structure of corundum. The oxygen ions form a hexagonal close-packed structure and the iron (III) ions occupy 2/3 of the octahedral interstices. In γ-hematite the oxygen ions form a cubic close-packed structure. The iron ions occupy 1/8 of the tetrahedral and 5/12 of the octahedral interstices. When γ-hematite is heated to a temperature of ca. 500 °C, it is irreversibly transformed into α-hematite.

In *magnetite* [*1317-61-9*] 1/3 of the iron ions are divalent, 2/3 trivalent. As in the case of γ-hematite, the oxygen ions form a cubic close-packed structure. The distribution of the cations over the interstices corresponds to that of the inverse spinel structure, i.e., half of the iron (III) ions occupy 1/8 of the tetrahedral interstices and the other half of the iron (III) ions, together with the iron (II) ions, occupy 6/12 of the octahedral interstices. The occupation of the interstices differs only slightly from that in γ-hematite, corresponding to the difference in the iron: oxygen ratio. The properties of both oxides are similar, as a result of the similar crystal structure. They are both ferrimagnetic, optically isotropic and have good electric conductivities compared to α-hematite.

Wustite [*1345-25-1*] is the oxide of divalent iron; however, it should be noted that the iron: oxygen ratio does not correspond to the stoichiometric value of unity. The oxygen ions form a cubic close-packed sublattice. The iron ions occupy the octahedral interstices but leave a certain number unoccupied. The overall lattice, therefore, corresponds to a defect NaCl type lattice. Wustite is electrically neutral because a portion of the Fe^{2+} ions has been replaced by Fe^{3+} ions. Wustite is thermodynamically stable at temperatures > 571 °C [9]. Below this temperature wustite disproportionates into magnetite and iron (eutectoid reaction). The rate of this disproportionation decreases rapidly with decreasing temperature. At room temperature wustite is, therefore, stable for an unlimited period of time.

(Commercially important iron compounds → Iron Compounds.)

2. Production

In the terminology a distinction is made between *primary reduction* (iron production), which is the subject of the present chapter, and *refining* (→ Steel). The production of iron can take place in the *blast furnace* which produces pig iron, or by means of other processes which yield equivalents such as sponge iron. Steel production refers to the processing step that involves the refining and the adjustment of certain solute contents in the iron (steel), irrespective of whether the raw material is crude iron, scrap, or sponge iron. This separation of processes is useful because the properties of steel (hot formability, strength) are acquired during the process of steelmaking and steel differs from raw materials such as pig iron and sponge iron with respect to these properties.

The most important metallurgical processing units for the manufacture of large quantities of liquid crude steel from ore are:

- for ore preparation
  - sintering plants
- for the reduction of oxide ores
  - blast furnaces
- for refining and alloying of steel and for scrap melting
  - converters operated with pure oxygen
  - open hearth furnaces
  - electric arc furnaces

Figure 1. Schematic flow sheet of steel production
a) Pelletizing drum; b) Sintering grate; c) Coking plant; d) Blast furnace; e) Torpedo ladle; f) Pig-casting plant; g) Basic oxygen converter; h) Siemens – Martin furnace; i) Electric arc furnace; j) Continuous casting; k) Soak pit; l) Ingot casting; m) To rolling mill; n) To shipping

The majority of the crude steel is processed to semifinished products by ingot casting or, increasingly, by continuous casting. A schematic representation of this important processing route from iron to steel is shown in Figure 1.

In addition to the blast furnace process, oxygen converter, open hearth furnace, and electric arc furnace, there are some other steelmaking processes. Although these are less important in terms of the relative quantity of steel produced, their production in absolute terms is significant. The quantity of raw steel produced annually in these units (30 Mt/a) is equivalent to the annual production of all other metals combined.

2.1. Raw and Auxiliary Materials

The *raw materials* required for iron production are:

iron ore and scrap iron
solid, liquid, or gaseous reducing agents
solid, liquid, or gaseous fuels to supply the heat needed for reaction and melting.

In the theoretical analysis of the reactions, certain *auxiliary materials* appear to a limited extent or not at all, even though they are crucial from the process-engineering standpoint:

slag-forming agents such as silica and silicates; sources of calcium and magnesium such as limestone, dolomite, olivine; and coke – ash constituents;
refractory materials such as bricks made of silica, magnesite, dolomite chromite, or carbon.

2.1.1. Ores

Iron is the fourth most abundant element in the Earth's crust (4.7 wt %). In relation to the total mass of the Earth, iron is probably the most abundant element.

Iron is found in high concentration in ore deposits, where it occurs mainly as oxide. Table 3 lists the iron minerals of greatest industrial importance (along with some accompanying gangue minerals) and their relevant properties.

The only minerals of worldwide importance are hematite (specularite, Fe_2O_3), magnetite (Fe_3O_4) and limonite (FeOOH). Siderite ($FeCO_3$) finds limited use on a local basis. Other ores such as chamosite (an iron magnesium aluminosilicate) or pyrite are virtually not important for iron production any more.

Table 3. Important minerals in iron ores

Mineral	Chemical formula	Density, g/cm^3	Hardness (Mohs)	Specific susceptibility (order of magnitude)
Iron (for comparison)	Fe	7.88	4 – 5	
Magnetite	Fe_3O_4	5.2	5.5	10^{-1} – 1
Specularite ("hematite")	Fe_2O_3	5.2 – 5.3	6.5	10^{-4}
Limonite				
Needle ore	α-FeOOH	4.3	5 – 5.5	10^{-6} – 10^{-5}
Ruby mica	β-FeOOH	4.0	5	10^{-6} – 10^{-5}
Siderite	$FeCO_3$	3.7 – 3.9	4 – 4.5	10^{-6}
Pyrite	FeS_2	5.0 – 5.2	6 – 6.5	10^{-6}
Phyrrhotite	FeS	4.6	4	10^{-3} – 10^{-4}
Chalcopyrite	$CuFeS_2$	4.1 – 4.3	3.5 – 4	10^{-5} – 10^{-6}
Apatite	$Ca_5F(PO_4)_3$	3.2	5	-10^{-6}
Vivianite	$Fe_3(PO_4)_2 \cdot 8\,H_2O$	2.6 – 2.77	3	
Quartz	SiO_2	2.65	7	-10^{-6}
Orthoclase	$KAlSi_3O_8$	2.55	6	10^{-6}
Plagioclase	$NaAlSi_3O_8/CaAl_2Si_2O_8$	2.6 – 2.8	6 – 6.5	10^{-6}
Kaolinite, dickite	$Al_4(OH)_8Si_4O_{10}$	2.6	1	
Muskovite	$KAl_2(OH,F)_2\,[AlSi_3O_{10}]$	2.6 – 2.8	2 – 2.5	10^{-2} – 10^{-5}
Pyrolusite	MnO_2	5	1 – 6	10^{-6}
Calcite	$CaCO_3$	2.6 – 2.8	3	-10^{-6}
Ilmenite	$FeTiO_3$	4.5 – 5	5 – 6	10^{-4}

2.1.1.1. Ore Deposits

Of the variety of classification systems that have been proposed for iron-ore deposits, the one from the United Nations Survey is used here [10]. The criterion is the physical appearance of the deposit; the main types are bedded (A), massive (B), residual (C), byproduct (D) and other (E).

A Bedded Deposits
A-1 *Iron Formation*
Lake Superior Type
Chiefly Precambrian; primarily as sedimentary deposits, heavily metamorphized (itabirite, taconite, jaspilite or quartz-banded ore); enriched by weathering processes (Mesabi, Minas Gerais, Carajas, Venezuela, Labrador and Quebec, Krivoi Rog)
Algoma Type
Primarily as thinly-banded quartzite with interlayers of iron ore; enriched as limonite – hematite weathering ore
A-2 *Ironstone Formation*
Mainly marine sedimentary deposits of minette type; Clinton, Wabana; chiefly mesozoic, with limonite as the most important mineral
A-3 *Other Iron-Ore Sediments*
Examples: clastic deposits, ferruginous sandstone, and iron shale; also alluvial deposits and unconsolidated clastic sediments

B Massive Deposits
B-1 *Bilbao Type*
Deposits from weathering of siderite rock, with limonite and hematite in the weathering zone
B-2 *Magnitnaya Type*
Contact-metasomatic replacement deposits
B-3 *Kiruna Type*
Magnetite intrusion, usually with apatite
B-4 *Taberg Type*
Syngenetic titanomagnetite bodies and deposits of finely-intergrown ilmenite ores

C Residual Deposits
C-1 Laterite and iron-ore caps as a result of weathering of underlying iron-bearing rocks
C-2 Fluvial deposits and bog ore
C-3 Other residual ores, e.g., caps of sulfide ore deposits (gossan, "iron hat"), unconsolidated clastic deposits

D Byproducts
Recoverable values in byproduct iron oxide

E Other Types of Deposits
e.g., lode-type deposits (Siegerland)

Bedded deposits are stratigraphic members enriched in iron by a factor of ca. 4 – 12 above average. They occur in all geologic ages; including ores which originate from them, they account for ca. nine-tenths of potential iron reserves. Names applied to Precambrian metamorphic ore beds are itabirite, taconite, Lake Superior type, quartz-banded ore, jaspilite, magnetite quartzite, hematite quartzite, etc. More recent formations are known as minette (Jurassic), Salzgitter type, and other local names. In general, the term bedded deposits is used for iron-mineral enrichments in which ore minerals are more or less closely laminated with quartz, jasper or carbonate rock and the iron-bearing sediments lie conformally to the under- and overlying beds of igneous or metasedimentary rock. Thus, iron formations can be chemical rocks, clastic sediments, or rock beds that have been replaced by iron mineral during diagenesis or in their subsequent history.

Massive iron-ore deposits are ore bodies of irregular shape, discordantly embedded in the enclosing rock. They include (1) replacement deposits in carbonate rocks (Bilbao type) with siderite, hematite or limonite (the last two in the weathering zone above the water table); (2) contact-metasomatic deposits in the contact region of acidic intrusive rocks with magnetite and, to a lesser extent, hematite, siderite, pyrite, pyrrhotite and copper sulfide (Magnitnaya type); (3) magnetite intrusions in acidic magmatic rock (Kiruna type); and (4) massive or intergrown titanomagnetite or ilmenite concentrations in basic rock (Taberg type).

The most important type of *residual deposit* is laterite, which occurs as a cap overlying a wide variety of rocks. It is the product of weathering in tropical and subtropical climatic regions. The iron content of these ores is usually low (limonite, hematite), the alumina content high, and undesirable accessory constituents such as chromium, phosphorus, and nickel are frequently present (e.g., at Vogelsberg, Germany). Thus, laterite has largely ceased to be an important iron ore except where the lateritic caps of other iron ore deposits have secondary enrichments of up to 69 % iron. On the other hand, nickel-bearing laterites are the most important nickel ores of the future (Cuba, New Caledonia, the Philippines). Extended fluvial deposits, such as the Robe River deposit in Western Australia, should also be mentioned. Bog ores, in contrast, form deposits of small extent that were formerly locally important. They are precipitation products from iron-containing solutions. The weathering cap of sulfide deposits (gossan or "iron hat"), which are usually separated from the primary sulfides by an indistinct boundary, are of some importance.

2.1.1.2. Supply of Iron Ore

Until about the 1950s, ironworks were mainly supplied from their own deposits; ore and concentrate were transported over short distances. Since that time a fundamental change has occurred as a result of (1) the greater demand because of increased production, (2) the drop in the cost of overseas transport because of larger ship capacities, and (3) the need for higher productivity because of continually rising labor and energy costs. The iron ore demand of the most important steel-producing regions is essentially met by a few large ore-producing regions.

Medium-sized and small ironworks located at deposit are now found only in case of large deposits (northeast India, the Ukraine and other areas of the Former Soviet Union, northeast China). Table 4, listing world iron-ore reserves, also shows, from the tonnage standpoint, that only a few countries play important roles in ore supply. The short descriptions below are limited to the most important deposit areas and supplier countries.

Table 4. World iron-ore reserves [11]

	Reserves, $t \times 10^6$	Iron content, %
Former Soviet Union	110 750	25.4
China	42 000	30.0
Brazil	34 540	56.9
Canada	26 417	31.6
United States	25 400	20.7
Australia	17 781	60.0
India	13 500	61.5
South Africa	6 300	59.1
France	4064	40.2
Sweden	3 353	59.1
Venezuela	2 337	54.4
Liberia	1 668	39.5
Other	2 235	28.4
World total	290 235	35.4

Production figures for iron ore, ore concentrate, and ore agglomerate appear in Table 5.

Table 5. World iron-ore production, ore, concentrate and agglomerate (1975 – 1993) (t × 10^6) [12, 13]

	1975	1980	1986	1993
North America	132.0	127.1	82.8	96.0
Canada	46.9	48.8	36.1	32.3
Mexico	5.1	7.6	7.3	8.0
United States	80.1	70.7	39.4	35.7
South America	134.3	146.1	164.7	189.8
Brazil	89.9	114.7	132.0	169.4
Chile	11.0	8.6	7.0	7.0
Peru	7.8	5.7	5.0	5.2
Venezuela	24.8	16.1	19.1	15.5
Europe	355.5	335.3	313.6	184.2
Austria	3.8	3.2	3.1	1.4
France	49.6	29.0	12.4	3.5
Germany	3.3	1.9	0.7	0.1
Norway	4.1	3.9	3.7	2.2
Spain	7.6	9.2	6.1	2.5
Sweden	30.9	27.2	20.5	18.7
Former Soviet Union	232.8	244.7	249.9	154.0
United Kingdom	4.5	0.9	0.3	
Former Yugoslavia	5.2	4.5	6.7	0.3
Asia	122.7	122.8	151.9	303.8
China	65.0	68.1	90.0	224.7
India	41.4	41.9	47.8	56.0
North Korea	9.4	8.0	8.0	10.0
Turkey	2.4	2.6	4.0	5.1
Africa	57.7	60.8	55.8	44.2
Algeria	3.2	3.5	3.4	2.6
Liberia	24.0	18.2	15.3	
Mauretania	8.7	8.9	8.9	9.2
South Africa	12.3	26.3	24.5	29.4
Oceania	99.9	99.2	92.5	123.7
Australia	97.6	95.5	90.0	121.4
New Zealand	2.3	3.6	2.4	2.3
World total	902.0	891.3	861.3	941.7

It is striking that the most important supply sources are type A deposits (bedded), and among these the metamorphic deposits of Itabira type (under that or some other local name), chiefly of Precambrian age.

Especially important are the enrichment or weathering zones of these deposits, where the mobilization of silica and alumina has produced rich ores that can be forwarded to ironworks without preliminary beneficiation. Table 5 also shows that ores expensive to produce and those whose beneficiation does not yield concentrates with at least ca. 60 wt % iron have lost much of their importance. In fact, most of them will no longer be in production after a few years. Examples are the Mesozoic deposits in France, Belgium and Luxembourg (minettes), in the United Kingdom (home ore) and in the Federal Republic of Germany (Salzgitter, Siegerland, Lahn – Dill, Oberpfalz).

The important producer countries rank as follows by tonnage output (1993 production, 10^6 t):

1)	China	224.7
2)	Brazil	159.4
3)	Former Soviet Union	154.0
4)	Australia	121.4
5)	India	56.0
6)	United States	55.7
7)	Canada	32.3
8)	South Africa	29.4
9)	Sweden	18.7
10)	Venezuela	17.5

2.1.1.3. Most Important Iron-Producing Countries [10 – 12, 14, 15]

Brazil. Brazil is currently (ca. 2000) the biggest producer of ore for *overseas shipment.* Two ore districts are now in production. The "iron quadrangle" ("Quadrilatero ferrifero") in Minas Gerais state is the more important. It sup-

plies several local ironworks, but most of the product is exported.

The ores occur in three successive beds, Precambrian in age and strongly metamorphized, called (from shallowest to deepest) Rio das Velhas, Minas, and Italcolomi [10]. The ore is thought to consist of marine sedimentary deposits. The ore beds contain 35 wt % – 60 wt % iron.

Various ore types are distinguished:

(1) hematite enrichments (lump to powder ore), > 64 wt % iron; (2) silica-rich hematite ore, 60 – 64 wt % iron; (3) itabirite, 35 – 60 wt % iron, occurring in compact, soft and powder forms and typical of the Minas series; and (4) Canga, (60 – 68 wt % iron), a conglomerate-like ore that often consists of rounded fragments in a limonite matrix. Capacity is ca. 130×10^6 t/a of ore shipped; about a tenth is shipped as lump ore, 24×10^6 t/a as pellets, and the remainder as sinter fine ore ("sinter feed").

The second large ore district is Carajas, with a production target of 35×10^6 t/a, 10 – 20 % of this being lump ore. The Carajas ore also lies within Precambrian beds and has been enriched by secondary processes to 60 – 67 wt % iron.

Venezuela [10, 15]. The most important iron-ore district is the Imataca belt, including the well-known Cerro Bolivar, El Pao, and San Isidro deposits. The belt is part of the Precambrian Guyana Shield. The ores occur in a sequence of metamorphic rocks with gneiss, shales, and taconite-like iron-banded quartzite. Secondary processes have created rich ore deposits, partly through the precipitation of iron hydroxide in cavities. At the surface, a hematite-rich laterite cap, 1 – 50 m thick has formed; this is still the main source of ore. In 1987, ore output was 17.2×10^6 t, of which 5.5×10^6 t was consumed domestically.

Lump ore, sintered fine ore and pellet feed containing 62 – 67 wt % iron, 0.6 – 6 wt % silica, 1–2 wt % alumina and 2 – 5 wt % loss on ignition are produced. To meet the needs of direct reduction units (Midrex, HyL, see Section 2.6) at the Matanza ironworks, a 6 600 000 t/a pellet plant has been erected.

Canada. The Labrador geosyncline is the most important ore district. Precambrian deposits of the Lake Superior type are regarded genetically as continental shelf deposits that have undergone various degrees of metamorphosis. There are weathered rich ores containing over 60 % Fe and having high limonite contents; weathered, relatively coarse-grained magnetite hematite ores containing 20 – 50 % quartz; and unweathered banded ore.

United States—Lake Superior. Most of the known iron-ore reserves in the United States are found in the Lake Superior area, in Minnesota, Wisconsin, and Michigan. About three-quarters of U.S. ore production comes from this region; the output goes to ironworks south of the Great Lakes (Ohio, Pennsylvania). The deposits occur in Lower and Middle Precambrian strata. Iron oxide, carbonate, silicate and sulfides are thinly banded with gel quartz and other gangue minerals. The thickness is between 15 and 300 m. Fine-grained magnetite and hematite are the principal ore minerals.

In weathering zones locally enriched lump ores exist containing ca. 60 % Fe; these consist of hematite and limonite. Mining is limited to these rich ores and magnetite-bearing beds, which are relatively easy to beneficiate by magnetic separation.

Australia. The large iron-ore reserves of this continent are concentrated in the north of Western Australia, in the Pilbara district. The Precambrian banded itabirite ores contain magnetite, quartz, carbonate, and stilpnomelane. The near-surface region includes hematite and limonite weathering ores. Besides these in situ enrichments, conglomerate and residual ores are also found; the latter have a high limonite content and occur chiefly in old Tertiary riverbeds.

India. In India the most important ore deposits are enclosed in the strata of a Precambrian geosyncline, which runs parallel to the east coast over a significant part of the subcontinent. The ore is mainly of itabirite type; lateritic weathering has produced rich ore with a high alumina content in the gangue, which extends to a considerable depth. Locally, quartzbanded lean ore and similar primary ores have also been exploited. Hematite ore containing > 60 wt % iron is worked; it is partly lump ore and partly sinter fine ore. Hematite – limonite ore also occurs. The lateritic hard-ore cap is often underlain by

blue dust. This ore consists of medium- to fine-grained primary specularite, martite and, locally, primary magnetite as weathering residue, and contains only small amounts of quartz, kaoline minerals, and gibbsite as gangue.

China. China has many isolated ore deposits, most of which form the basis for local iron and steel industries. The largest concentration of reserves, however, is in the provinces of Liaoning (northeast China) and Hebei (eastern central China). The ores are of itabirite type, mainly with hematite – quartzite ores containing 50 wt % iron. Large rich ore reserves are obviously nonexisting in China. Of the ores now being mined, it is known that beneficiation is often difficult and costly. Exceptions are the various magnetite deposits of Magnitnaya type. Some ores contain undesirable secondary constituents such as tin, fluorspar and finely intergrown apatite. Despite the potential reserves, cost considerations may cause China to import iron-rich ore; the recently observed construction of steelworks at coastal sites is an indication of this policy.

Former Soviet Union. The Former Soviet Union has more than 20 iron-ore regions. The most important reserves are in the regions of Kursk, western Siberia, and the Ukrainian crystalline shield. The first two areas account for ca. 30 % each, the last for some 10 % of the Former Soviet Union's total reserves [10]. The most important production region is the Ukrainian Shield, with the Krivoi Rog syncline as its center ("Krivbas"). The Precambrian strata here contain both magnetite – quartzite and hematite – martite – quartzite ores.

In the area of the *Kursk Magnetic Anomaly,* three basins are distinguished: Belgorod in the west, Kursk-Orel in the center, and Staryi Oskol in the east. Near-surface rich ore with hematite and martite has been exploited for some time. The horizontal quartzite – magnetite beds are of increasing economic importance. From the geological standpoint, the iron-bearing beds form part of the Precambrian basement of the Central Russian shield.

In the *western Siberian* ore province, three districts exist. However, only the *Kuznetsk – Sayan* area has acquired economic importance. It consists of a large number of contact-metasomatic magnetite ore bodies of slight and moderate thickness, which also contain iron sulfide and zinc sulfide. The deposits are thought to have originated in the time of the Caledonian orogenesis.

The *Gornyi Altai* district has limited reserves in Clinton-type deposits (sedimentary deposits with partial secondary enrichment), which date from the Variscan orogenesis.

The western Siberian district, in a narrower sense, has considerable reserves of minette-type sedimentary ore deposits that have not been much explored; these had their genesis as marine coastal deposits in the Upper Cretaceous and the Eocene.

Sweden. For a long time, Sweden was the most important ore supplier for the Central European and, in part, the Western European iron industry. Quartz-banded magnetite – hematite ores of the Lake Superior type were mined in central Sweden. However, the chief source of ore for export is northern Lapland, in a district centered around Kiruna and Malmberget, where Kiruna type magnetite deposits (massive intrusions in granite-like enclosing rock, with a relatively high apatite content) occur. Reserves are more than 2×10^9 t, with ca. 60 wt % iron and 0.04 – 5 wt % phosphorus. The phosphorus content is reduced to 0.04 wt % by beneficiation, because hardly any Bessemer pig iron is produced in western Europe any more.

2.1.1.4. Beneficiation of Iron Ore

The purpose of beneficiation is to render the ore more suitable for transport and for various reduction and smelting processes in the production of pig iron or steel.

The only processing steps used for ores mined from rich deposits (rich ores) are crushing and screening. Such ores come mainly from the weathering zones of itabirite deposits. At some mines, washing is combined with the screening of fines ($< 6 - 8$ mm) for sintering; very fine material containing kaolin is thus separated, and the alumina content is reduced. Low-grade ore is *concentrated* to lower transport costs and bring about a chemical composition suitable for the subsequent reduction step. In this enrichment process, the gangue is reduced and, in many

cases, its composition improved. Current reduction and smelting processes require a basic slag ($CaO : SiO_2 > 1$), but the gangue, of nearly every type of iron ore, is "acidic", that is, it contains an excess of silica. Beneficiation lowers the silica level to 5 – 8 wt % in the concentrate.

Harmful components present in the ore must be removed. Such components include phosphorus, arsenic, chromium, copper, vanadium, alkali, sulfur and titanium; these either make metallurgical processing more difficult or degrade the iron and steel quality. A small quantity of titanium (< 0.5 %) is, however, added to the burden at some ironworks, because it has been found to increase the life of the blast-furnace brickwork.

The basic methods of beneficiation for iron ores are usually the same as for nonferrous ores and industrial minerals. Naturally some peculiarities exist because of the mineralogy and the type of intergrowth.

Crushing. Conventional equipment is employed for crushing (→ Size Reduction). Primary crushing takes place in *gyratory crushers* (up to 3500 t/h) or *jaw crushers.* Mobile versions of the latter are now employed directly at the mines. *Cone crushers* are common for the second and third stages of crushing. They are however, increasingly replaced by *semiautogenous grinding* (SAG). Here steel balls, 100 mm or greater in diameter are added in a quantity of up to 6 vol % to aid the comminuting action. *Autogenous mills* are tumbling mills of large diameter and relatively short length, roughly 0.4 – 1.2 times the diameter. *Fine grinding* takes place in *rod* and *ball mills,* usually in a closed circuit with classification by hydrocyclones. Both dry and wet comminution are practiced; the wet process is more common when this step is followed by concentration.

Another option is autogenous or semiautogenous primary crushing followed by fine grinding in a *pebble mill;* a tumbling mill which does not contain steel balls but lumps of ore of ca. 75 – 30 mm in diameter. This is possible only with hard ore that yields enough "pebbles" in the first crushing stage. This process has the advantage that no grinding balls are needed, but the energy requirement for grinding often increases if the conditions in the mill are not optimal.

Vibration screens with elliptical or linear oscillations have been widely adopted for screening. Multilevel screens of the Mogensen design are increasingly used.

Concentration. The concentration of iron ore is generally based on physical differences between the iron-bearing and gangue minerals (see Table 3). *Flotation* (→ Flotation) and *electrostatic concentration* (→ Electrostatic Separation) utilize physicochemical differences. The iron minerals have a higher specific gravity than the gangue minerals, so in many cases *gravity* (→ Gravity Concentration) or *centrifugal concentration* (→ Centrifuges, Filtering, → Centrifuges, Sedimenting, → Hydrocyclones) is possible. The *dense-media separation* (→ Dense-Medium Separation) process for coarse particles (≥ 3 mm) in drum or tank separators is also used. For medium-sized material, ca. 15 – 0.5 mm, cyclone separators or the cylindrical "Dyna Whirlpool" can be employed. Both use a centrifugal force field for separation. Gravity separators for fines (roughly 2 – 0.075 mm) include the Humphreys' spiral concentrator and the Reichert cone separator.

The Reichert cone separator has been adopted in the past two decades mainly for the beneficiation of placer ore, but it is used more and more for fine-grained weathering iron ores.

The *magnetic concentration* (→ Magnetic Separation) of magnetite ore takes place in drum-type separators with a low-intensity magnetic field. Dry separators are fed from the top and discharge the nonmagnetics, in wet separation the ferromagnetics are picked up from the feed pulp (underfeed). Ferrite-based permanent magnets have almost completely replaced ALNICO and electromagnets. The magnetic flux density is up to 0.15 T. Wet separators include drums up to 1500 mm in diameter and 3600 mm wide, with throughput capacities of 50 – 200 t/h. The drums, with up to five poles, are arranged in appropriately designed tanks for cocurrent or countercurrent operation. In addition, *high-intensity wet* magnetic separators have been employed since ca. 1970 in the concentration of weakly magnetic ore. The Jones design is most common. Here the separating elements are arranged in a ring which rotates carousel-fashion through a strong field generated by electromagnets. The magnetic flux density in the separation zone is 0.1 – 0.5 T; because of the tip configuration of the separating elements, it is concentrated at the tips to much higher values with a strong

convergence of the field lines. The carousel design permits semicontinuous operation.

High-intensity dry magnetic separators are generally not used in beneficiation any longer. Electrostatic drum type separators are employed only for the recleaning of the concentrate, where they remove mainly quartz-bearing gangue. The process is restricted to grain sizes in the range of 1 – 0.05 mm.

Flotation has been used for iron-ore beneficiation since ca. 1950. The first two systems in Michigan were built for "direct" flotation (values in froth) of fine-grained specularite ore. Tall oil and diesel oil were added as collectors. "Hot flotation" enabled concentrates to float with only a few percent of silica. The rougher concentrate in pulp form was heated to $> 90\,^{\circ}C$, then recleaned in several stages after cooling. "Indirect" or "reverse" flotation is most commonly used today; the gangue goes into the froth and the iron ore into the underflow. Conditions are controlled so as to prevent the ore from flotation. As depressants for iron ore, starches or dextrin are used in conjunction with a basic pH. The collectors employed for gangue depend on the gangue minerals: oleic acid or oleates (e.g., for apatite) or amine salts (for quartz and feldspar). In general, the goal is first to enrich the ore as much as possible by less expensive means (gravitiy, magnetic separation), using relatively expensive flotation only for the final beneficiation stage. In the case of rich ores, however, flotation can also be employed as the sole concentration process when only a little gangue is to be removed.

A process of limited importance is *magnetizing roasting* followed by low-intensity magnetic separation. The iron minerals are thermally converted to magnetite with solid, liquid or gaseous reducing agents. The process is used in shaft furnaces in China and rotary kilns in the Former Soviet Union.

A *thermal* beneficiation process is the roasting of siderite ore. The purpose of this process is to save weight for transport and to relieve the blast furnace of the carbon dioxide load. Shaft furnaces or sintering machines are employed. In the latter case, agglomeration is combined with calcination.

Figure 2 presents a general flowsheet for the beneficiation of iron ore. Currently (ca. 2000) almost all the crude ore comes from large-scale open pit mines with capacities between 10 000 and 100 000 t/d. Only in Swedish Lapland, the Former Soviet Union and China are high-capacity underground mines operated. Depending on the iron content and other requirements, the ore is processed into lumps, sinter or pellets; Table 6 lists the fractions of these products in blast-furnace burdens in several areas. Table 7 gives some analyses of ores that are of commercial importance.

Figure 2. Schematic diagram of iron-ore processing

The beneficiation of an Indian laterite ore is shown schematically in Figure 3. The ore is a decomposition product containing limonite and hematite values along with kaolin, quartz and alumina minerals as gangue. By washing in a drum and then removing the finest fraction, the iron content is elevated by ca. 3 % units and the Al_2O_3 content is lowered from 3 – 4 % to < 1.7 wt %.

This simple way of improving the composition of iron-rich fine ore is often used in India and Brazil. A basically similar process with washing troughs or log washers was formerly used for high-alumina ores in many other regions (Salzgitter, Ilsede, Mesabi Range). If much of the alumina present is associated with limonite, a rod mill is employed instead of a washing drum. Applying 3 – 4 kWh/t on comminution frequently results in satisfactory removal of alumina. Figure 4 illustrates the beneficiation of a magnetite ore from a Magnitnaya-type deposit. Secondary and tertiary crushing and primary grinding are replaced by an autogenous mill. The concentrate has ca. 69 wt % iron; with a particle-size distribution of ca. 80 % $<$ 0.045 mm, which is fine enough for pipeline transportation and pelletizing. Numerous beneficiation plants for magnetite ore from other deposit types have been designed in a similar way, for example in the Former Soviet Union (Krivoi Rog, Kursk, Olenogorsk), in the Lake Superior area, and in northern Sweden. Older installations still employ conventional comminution (three stages of crushing and two to three stages of grinding). For hematite ore, the first grinding stage is followed by gravity separation or, in the case of fine grained ore, further grinding is followed by high-

intensity wet magnetic separation or flotation. In many cases, however, the principal iron minerals in such ores from weathering zones include not only hematite but martite (which is only a little less magnetizable than magnetite) with residual magnetite. In this case, complex flowsheets must be adopted, including low- and high-intensity magnetic separation, flotation, classification and slurry treatment for dewatering of the concentrate. This is also the case if undesirable constituents are present (e.g., apatite).

Finally, the *selective dispersion* process should be mentioned. In one Michigan plant, this operation is a preliminary to flotation. After grinding to the liberation size, sodium hydroxide and starch are added to the ore pulp (sodium hydroxide to disperse aluminous and limonitic constituents, starch to flocculate the specularite) and the flocculated agglomerates are separated from the dispersed minerals in a hydroseparator. The downstream flotation removes coarse quartz which is discharged in a conventional manner, with amine salts as collectors.

2.1.1.5. Agglomeration

In present-day smelting technology, very fine material is undesirable in the reduction equipment. The blast furnace is the dominant type of equipment for the production of iron metal. Only in exceptional cases (small furnaces with capacities up to ca. 100 – 150 t/d of pig iron) is unscreened crude ore used (after primary crushing if necessary). Modern high-performance blast furnaces require physical and metallurgical preparation of the burden. Formerly agglomeration was used in a purely physical way, as a process of size enlargement aimed at improving the permeability of the blast-furnace burden; however, developments in recent years have shifted part of the slagging into the fine-ore or concentrate sintering step. On the other hand, the requirements for physical and chemical quality of the blast furnace burden have become more stringent, and mining companies that supply ore to several ironworks (as the large ones generally do) now prepare a variety of concentrate or fine ore qualities from the same or similar crude ores.

As a rule, blast-furnace burden contains lump ore, sinter, and pellets. *Pellets* are made from both concentrate and iron-rich fine ore (see Fig. 1). If the beneficiation process yields very fine-grained concentrates (e.g., < 0.1 mm), these are usually converted to pellets at the mine and transported in this form. *Sinter* is generally produced at the ironworks. The varying loads imposed on material during transport to the blast furnace mean that pellets must satisfy stringent mechanical strength requirements. Pellets are also nearly always made from one well-defined ore or concentrate, whereas sinter is produced from predesigned mixtures of ores and additives. There are exceptions, such as pellets made at ironworks from mixed ore, or sinter made from a single ore or concentrate quality where an ironworks uses ore from a single deposit. Blast furnaces are also sometimes operated with lump ore alone, sinter alone, or pellets alone. Sponge iron plants are generally fed with a single iron source.

Sinter and pellets differ in the way the particles are bound into the agglomerate. In pellets, the ore particles are connected chiefly by bridges of ore. When magnetite is oxidized at temperatures > 900 °C during hardening of pellets, these bridges arise through mobilization of lattice constituents during recrystallization into the hematite lattice. In the case of hematite ores, mobilization is less pronounced, because the crystal lattice structure does not change. The formation of iron oxide bridges is supported by additional slag bridges; it must be remembered that the quantity of slag in many pellet qualities is only 3 – 4 wt % (corresponding to 6 – 7 vol %).

Sinter consists of a calcium ferrite matrix, with siliceous and aluminous constituents dissolved and primary hematite embedded in it. Whereas pellets are thoroughly oxidized (a maximum of 0.5 wt % FeO), sinter contains 4 – 6 wt % FeO, which is linked to silica and alumina in the matrix.

Pellets are burned at a temperature below the melting points of the constituents. Their strength gain is adequate only when the reaction temperature is controlled to $\pm$ 10 °C over long time periods. For this reason, hot gas is used to supply heat; it can be generated by the combustion of fuel gas, oil, or even coal. In sintering, on the other hand, the constituents of the mixture are melted. This happens at temperatures so high that the reaction itself goes to completion within minutes, but in a thin layer that continuously advances through the material bed cocurrently to the gas. The fuel is coke breeze, or occasionally

non-gassing coal fines, evenly distributed in the sinter mixture.

Pelletizing. Iron-ore pellets are made in two steps. The concentrate to be pelleted must have a sufficiently fine particle-size distribution (65 – 85 wt % $<$ 0.045 mm) and a specific surface area of at least 1600 cm^2/g as measured by a permeability method (Blaine, Fisher Subsieve Sizer).

Spherical *green pellets* (green balls) of appropriate size (ca. 9 – 16 mm in diameter) are formed by a pelletizing disk or drum. The particles are bound together by capillary forces acting through water bridges between them. This means that green pellets can be obtained only at a narrow range of moisture content. If the water content in the fine ore (which is usually recovered as a filter cake) is too high, water-absorbent materials such as bentonite can be used to correct it within narrow limits. If the water content is low (ideal case) it is useful to hold it in the filter cake ca. 0.5 – 1 % lower than the green pellet moisture content to suppress the premature formation of undersize pellets ("micropellets") in the granulator.

Prior to (or during) the formation of green pellets, substances are added to the fines to render them stable against the stresses that occur in the hardening process. In addition to bentonite, whose active constituent is strongly water-absorbent montmorillonite, organic binders such as Peridur have come into use. The latter are advantageous in that they can be burned off during hardening, whereas bentonite elevates the silica and alumina content of the pellets.

Purchasers usually prescribe the gangue composition of pellets to fit the operating requirements of the particular blast furnace and the chemical composition of the other iron sources to be used. This composition, which also governs the chemical and metallurgical properties of the pellets, is controlled with additives, the most im-

Figure 6. Flowsheet of combined traveling grate/rotary kiln ("grate kiln") process
a) Traveling grate; b) Rotary kiln; c) Annular coolers

portant being slaked lime, limestone, dolomite and olivine. These are added in a grain size corresponding to that of the fines.

The second operation is the *thermal hardening* of the pellets at 1200 – 1320 °C. Nonthermal hardening is employed only in a few unimportant cases. Three distinct heat hardening systems exist: the traveling grate (see Fig. 5), the combination of preheating traveling grate and rotary kiln (grate – kiln) (see Fig. 6), and the shaft furnace. The shaft furnace is mainly suitable for magnetite concentrates and low capacities (up to ca. 500 000 t/a) and has lost much of its market share in the past 15 years. The traveling grate and the grate – kiln combination each share ca. 50 % of the market.

The "basicity" of the final pellets, expressed as the ratio $(CaO + MgO) : (SiO_2 + Al_2O_3)$, is $<$ 0.1 for "acid pellets" or up to 1.3 for "basic pellets". Each range of values offers certain advantages and disadvantages with respect to mechanical strength and metallurgical qualities.

After a number of years of declining pellet production and the shutdown of several plants, the western world had, at the end of 1987, a pellet capacity of roughly 163×10^6 t/a (100 units using the three hardening processes).

According to present information, the Former Soviet Union has 20 traveling-grate plants and 5 grate – kiln plants. The first group has a total reaction area of ca. 6500 m^2, which might correspond to a pellet capacity of ca. 50×10^6 t/a. Grate – kiln plants add an estimated capacity of ca. 10^7 t/a.

While the Former Soviet Union has a large number of pellet plants, up to now this has not been the case for China.

For the assessment of the mechanical and metallurgical properties of burned pellets, a number of parameters are determined in more-or-less standardized tests. The most important are:

1) Cold Compression Strength. Individual pellets 10 – 12 mm in diameter are compressed to failure between two plane or slightly concave faces of a hydraulic press, and the crushing force is measured (values found in practice are usually $>$ 3000 N per pellet).
2) Abrasion Resistance. The abrasion resistance is determined in the ISO tumble test. Under standardized conditions, pellets are tumbled in a drum and the $>$ 6.3 mm and $<$ 0.6 mm fractions are determined. The values should be at least 95 % and at most 4 %, respectively.
3) Low-Temperature Disintegration Test. This test indicates how the pellets will behave, for example, in the blast furnace in the critical range of temperatures around 500 °C. In an electrically heated rotary kiln, pellets are heated to 500 $\pm$ 10 °C and held at this temperature for 60 min under reducing conditions. After cooling, the pellets are screened to determine the $>$ 6.3 mm and $<$ 0.5 mm fractions. The degree of reduction is determined. The values for the $>$ 6.3 mm fraction are usually between 60 and 80 wt %; those for $<$ 0.5 mm usually 10 – 20 wt %.

Figure 7. Flowsheet of sintering
a) Mixing drum; b) Travelling grate; c) Gas distribution hood (EOS only); d) Annular cooler; e) Waste-gas fan; f) EOS recycling gas fan; g) Fresh air blower (EOS only); h) Waste-gas final cleaning
EOS = Emission-optimized sintering

4) Free Swelling. In a vertical tubular furnace, 18 pellets are reduced with a carbon monoxide – hydrogen mixture at 1000 °C. The weight loss during reduction yields the degree of reduction. The volume change in the pellets indicates the swelling, which should be 20 % at maximum. The compression strength measured in a hydraulic press should be > 500 N per pellet.
5) Reduction under Load (RUL). In an upright retort, pellets are heated to 1050 °C, placed under a mechanical load of 5 N/cm^2, and exposed to a reducing atmosphere. The pressure drop of the reducing gas across the bed and the reduction rate are determined. A low pressure drop indicates pellets stable in reduction. The pressure drop should not exceed 100 Pa.

The reduction rate at 40 % reduction is an important parameter of reducibility; dR/dt_{40} should be at least 1 % per minute.

Special test methods have been devised for pellets used in various direct-reduction processes (HyL reduction test in an upright retort, Midrex test, and testing for the SL/RN process in an electrically heated laboratory rotary kiln). In the test for the SL/RN process, pellets and reducing agent (usually coal) are investigated at the same time. A number of different or modified test procedures are employed in individual countries or at individual ironworks.

Sintering. Iron-ore sinters are virtually all produced in traveling-grate installations (see Fig. 7). The rotary kiln and pan-sintering processes formerly in use are no longer important. Likewise, cooling of the hot sinter at the last section of the grate has become obsolete. Current standard is reflected by the straight-grate "Dwight – Lloyd process". Straight-grate and annular coolers are in use. Quite some effort is being made to reduce the level of solid and gaseous contaminants in the sintering off-gas (dust, SO_2, NO_x). A new development recently introduced by Lurgi in industrial plants is the Emission Optimized Sintering (EOS) process. In the EOS process approximately half of the off-gas of the sintering grate is recirculated

back to the gas distribution hood, where it is mixed with fresh air and used as oxygen carrier and heat transportation medium in the sinter bed. The advantages are reduction of the final waste-gas volume (and thus smaller waste-gas cleaning facilities) and substantial reduction of pollutants (dust, SO_2, NO_x, dioxins, furans) in the waste gas. Fuel consumption is lowered by about 5 kg per tonne of sinter, whereas the consumption of electrical energy is increased by about 1.5 kW h/t [18]. Sintering units are nearly always operated on site at the ironworks. As a rule, several ores are processed in one unit; a "monosinter" from just one ore is the exception. Along with ore and concentrate, the mixture for sintering also contains recycle material from the ironworks, provided no buildup of undesirable or detrimental substances results. Undersize sinter from the screening step is also recycled. The basicity of the sinter has been substantially increased in recent years. Originally sintering was considered only as a means to deal with fine ore with respect to improved handling and permeability of the blast-furnace burden ("physical burden processing"). The overall chemical composition of the blast furnace feed (including coke ash) was adjusted by addition of suitable materials in the form of lumps (limestone, dolomite, manganese ore if necessary). Thus, the basicity of sinter and lump ore generally was < 1 (exception minette ore with high calcite content of the gangue).

Today these additives are generally added to the sinter mix as fines (< 5 mm) and sometimes precalcined (burnt lime instead of limestone). The basicity of the sinter is generally higher than that of the blast furnace slag to compensate (1) for the "acid" coke ash, (2) the gangue of the lump ore, and (3) slag components of the iron-ore pellets. Increasing the basicity also improves the quality of the basic sinter as well as the heat economy. Many plants today produce sinter with a basicity of > 1.5. The slag analysis is controlled by addition of limestone or burnt lime, dolomite (to control CaO and MgO), olivine (to control MgO and SiO_2), and quartz sand. The most common fuel is coke breeze. To ignite the mixture gas or oil heating is applied. The total heat consumption for an iron-rich basic sinter is between 1.3 and 1.7 MJ per tonne of final sinter. When low-iron ore mixtures (e.g., those containing minettes) or ores containing high levels of alumina (2 – 4 wt % Al_2O_3) are sintered, the heat consumption is higher (up to 2.5 MJ/t). Analyses of sinter from German ironworks fall in the following approximate ranges:

Fe_{tot}	55.5 – 58 wt %
Fe(II)	4.5 – 6 wt %
SiO_2	5 – 6 wt %
CaO	9 – 11 wt %
MgO	1.2 – 3.2 wt %
Al_2O_3	1.2 – 2 wt %
$CaO : SiO_2$	1.4 – 1.9

Ironworks in the *Federal Republic of Germany* use imported ores almost exclusively; some heat-consumption and analysis figures for other European ironworks differ from the ones cited, because low-iron domestic ores still are processed there. In contrast, sintering plants in *Japan* operate under conditions similar to those in Germany. The basicity of the sinter in Japan, however, is nearly always > 1.8.

In the *United States,* the fraction of sinter in the burden is only 22.5 wt % (1986; see Table 6), much lower than in Europe and Japan. The fraction of pellets, on the other hand, is very high (72.2 wt %). Thus, in the United States improvement in pellet quality, above all in metallurgical properties, have been the focus of attention, with the result that basic pellets with $CaO : SiO_2$ ratio of ca. 1.5 have been sought.

Few details are known about current sintering technology in the *Former Soviet Union* and *China*. Rich fine ores are rare in both countries, and agglomerates are made chiefly from concentrates. In some works, blast furnaces are operated on 100 % sinter. Since the basicity of the sinter in these cases must be adapted to the requirements for blast-furnace operation, the basicity values are often too low for a sinter of truly good quality. One remedy might be to pelletize part of the concentrate at a low basicity and raise the basicity of the sinter to 1.6 – 1.8.

A variety of test methods are used for sinter quality control; some of the techniques are similar to the ones for pellets. The methods include:

1) Shatter Test. The shatter test has been standardized only in Japan. At Lurgi, 150 kg of sinter (grain size > 8 mm) is dropped three times from a height of 2 m onto a steel plate; then the > 20 mm, 20 – 8 mm, 8 – 2 mm and < 2 mm fractions are determined.
2) Tumble Test. The shatter test is often replaced by the tumble test, which follows the same guidelines as described above for pellets. The

Figure 8. Consumption of hot metal, scrap, and direct-reduced iron (DRI) for the production of crude steel in 1994 (average charge 1152 kg/t crude steel)

fraction < 6.3 mm should be at least 70 wt %; at German ironworks it is between 70 and 85 wt %.

3) Low-Temperature Disintegration (LTD). This test is done according to ISO 13930 known also as the dynamic disintegration test and mainly used for pellets and lump ores. A sample of 500 g (10 – 12.5 mm for pellets) is reduced at 500 °C in a rotating drum (150 mm in diameter and 540 mm in length). The gas mixture consists of 20 vol % CO, 20 vol % CO_2, 2 vol % H_2 and 58 vol % N_2. Reaction time is 60 min. The LTD index is the fraction > 6.3 mm.
4) Reduction Degradation Index (RDI). The reduction degradation index is now regarded as the most important quality criterion for sinter. Within ISO two test procedures exist to evaluate the RDI value, both known as static disintegration test. In ISO 4696–1 500 g of sinter (10 – 12.5 mm) in a stationary bed is reduced for 60 min at 500 °C by a gas mixture comprising 20 vol % CO, 20 vol % CO_2, 2 vol % H_2 and 58 vol % N_2. After cooling the sample is placed in a drum (130 mm in diameter, 200 mm in length, with two lifters) and subjected to 300 revolutions. The RDI index is > 3.15 mm. This test is normally used in Europe. In Germany, the value of > 3.15 mm is required to be > 70 % for sinter. In ISO 4696–2 500 g of sinter (16 – 20 mm) in a stationary bed is reduced for 30 min at 550 °C by a gas mixture comprising 30 vol % CO and 70 vol % N_2. After cooling the sample is placed in a drum (130 mm in diameter, 200 mm in length, with two lifters) and subjected to 900 revolutions. The RDI index is the fraction < 2.8 mm. This test is mainly used in Japan. The RDI index for sinter in Japan is between 30 and 40 wt %.
5) Relative Reducibility. Ironworks use very different methods for the relative reducibility test. A sample is reduced at 900 °C using a carbon monoxide – nitrogen mixture similar to RDI ISO 4996–2. The index reported is the degree of reduction at the end of the test. In addition, a test as set forth in ISO 4695 is carried out to determine the reduction rate at 40 % reduction, which is usually ca. 1.5 % per minute.

2.1.2. Reducing Agents [19, 20]

A considerable amount of heat input is required in the production of iron, because essentially all the processes involved are pyrometallurgic. Part of the heat is used to heat up the raw materials to be processed and part of it is required for endothermic chemical reactions. The majority of this energy is obtained by gasification of fossil fuels to reducing gas. Approximately 40 % of the annual output of steel is derived from scrap in *electric arc furnaces,* which pose a correspondingly high demand for thermoelectric energy. In 1995 the percentage shares of the different steel production methods were as follows: 60 % oxygen steel, 33 % electric furnace steel, and 7 % open hearth steel. The proportion of the obsolete open hearth steelmaking process is largely a result of the slow pace of change in Eastern Europe. In 1994 hot metal had a share of 57.5 % of metals used for world crude steel production and the percentage of scrap was 39.2 % (see Fig. 8) [21].

Reducing Agents. Carbon and hydrocarbon carriers, chiefly in the form of coke, are gasified to the primary reducing agents (CO, H_2) in blast furnaces. Coke can be replaced partly by carbon and by hydrocarbon carriers injected via the tuyeres. Examples of hydrocarbon carriers are coal, oil, natural gas, coke oven gas, or plastics wastes. But for physical reasons a blast furnace cannot be operated without coke. As iron ores change their chemical and physical properties from top to the hearth of the furnace according to reduction, softening and melting, the coke remains the only solid material below the smelting zone of the iron bearing materials. On the one hand, it forms a strong grid which supports part of the weight of the overlying burden and on the other hand, it constitutes a highly permeable "trickle column" (see Section 2.5) which allows an adequate drainage of the molten material's slag and hot metal and a good distribution of the gas ascending from the raceway at the tuyeres.

The coke plays a very important role in the so-called "cohesive zone", i.e., the region where the softening and melting iron-bearing materials are believed to form impermeable layers, separated by "coke windows". This is why a blast furnace operation without coke is not possible for physical reasons. In the blast furnace hearth the coke forms a cone, the so-called "dead man", which should be permeable for hot metal, slag and the furnace gas (see Section 2.5).

Requirements on Coke Properties. It is assumed that all the coke produced in a coke oven plant of an integrated iron and steel works will be used for the production of hot metal only. Concerning the grain size of the produced coke, the distribution of the size fractions to be used are, for example, 75 % "bell coke" (coarse coke) in the range of 30 to 80 mm, 17 % "nut coke" (small coke) in the range of 10 to 30 mm and 8 % "coke breeze" (coke fines) < 10 mm in size [22]. Coke quality requirements can be derived from the functions of coke in the blast furnace in conjunction with the mode of blast furnace operation. Table 8 lists the requirements on chemical composition and physical properties of coke for the operation of big blast furnaces with low coke rates, high productivities, and the production of hot metal with uniform chemical composition and temperature [23].

Table 8. Requirements on coke properties in Germany (Source VDEh Blast Furnace Committee)

Chemical composition	
Ash	< 9.0 wf % *
Volatile matter	< 0.75 wf %
Sulfur	< 0.7 wf %
Alkali	< 0.2 wf ($Na_2O + K_2O$)
Chlorine	< 0.05 wf %
Phosphorus	< 0.03 wf %
Zinc	< 0.003 wf %
Physical properties	
CSR	< 10 mm > 65 %
CRI	max. 23 %
Grain size (before drumming at delivery)	
> 100 mm	0 %
> 80 mm	max. 10 %
< 40 mm	max. 18 %
< 20 mm	max. 3 %

* wf = water free.

The ash content of the coke in itself is rarely a major problem for furnace operation, but nevertheless high coke ash can mean higher slag volumes and consequently higher energy consumption and lower furnace productivity. The main problems with coke ash are related to tramp elements. Especially alkalis and zinc have highly detrimental effects because they disturb the regularity of the furnace operation and entail a higher consumption of reducing agents as well

Figure 9. Schematic representation of the coke degradation in a blast furnace

as a loss in furnace productivity and in consistency of the quality of the hot metal.

Sulfur can be eliminated from the hot metal down to the required values partly by discharge with the blast furnace slag and partly by a separate desulfurization step prior to the steel shop, but its removal can become extremely costly. The use of sulfur-rich coke breeze in the sinter plant leads to higher SO_2 concentrations in the waste gas and to higher costs for waste gas cleaning. Both sulfur and alkalis should be discharged from the blast furnace via the slag. However, it is difficult to remove sulfur and alkalis simultaneously, because sulfur can only be chemically bound in a basic slag and removed from hot metal whilst alkalis can only be bound in an acid slag.

Coke moisture and chlorine content can be a problem for an efficient furnace operation, because both increase the dew point of the top gas. Thus, they either impose a thermally inefficient operation with higher top gas temperatures, or, if the top gas temperatures become too low, they cause condensation and corrosion in the gas lines and dedusting equipment. To maintain a good permeability of the blast furnace an excellent coke strength is important. Figure 9 shows a schematic representation of the coke degradation in a blast furnace [24]. The coke is attacked by mechanical load, by alkalis, and by gasification due to the Boudouard reaction. To guarantee the countercurrent principle of the process, the lumpy bell coke should change its grain size and grain form as little as possible up to the temperature of 1500 °C. Especially in the operation mode with low coke addition and high injection rates, the longer residence time of the coke in the very high temperature region and the supplementary abrasion by injected coal particles can enhance the coke degradation in the furnace bosh and at tuyere level [25]. Therefore, the coke must be stabilized, fissure free, and must have a cold strength I_{40} (IRSID-test) of more than 50 % plus 40 mm after tumbling.

In the hearth of the blast furnace the coke cone (dead man) must posses a sufficient permeability. Tapped volume of hot metal and slag and tapping time are closely related to coke size. Coke particles that are too small entail the formation of an impermeable inert central core in

the blast furnace, which deviates gas and liquid flow towards the walls of bosh and hearth. This can lead to disastrously rough furnace operation, wear of the refractory lining and breakouts [26].

High temperature properties of coke are generally expressed in terms of the CSR value (**C**oke **S**trength after **R**eaction with CO_2) and the CRI value (**C**oke **R**eactivity **I**ndex). Both values are measured in one single test procedure under gasification of a coke sample with CO_2 at 1100 °C. The CRI value is evaluated by analyzing the loss of coke weight and the CSR value expressed by the grain size portion > 10 mm after mechanical stress.

Figure 10. Limiting curves for the effective rate constant in the Boudouard reaction shown for two types of coke; – — coke type a; – – – coke type b (the curve parameter is the grain diameter in mm)
a) Chemical surface reaction; b) Boundary layer diffusion; c) Pore diffusion

Depending on coke temperature and particle size, the principal determinant in the rate of the Boudouard reaction

$$C + CO_2 \rightleftharpoons 2\,CO \tag{1}$$

is the varying resistance to reactivity. In the case of blast-furnace coke with a particle size between 40 and 80 mm, and at low temperature (< 1050 °C), the limiting factor is the resistance of the interfacial reaction. For particles < 8 mm in diameter the resistance of the interfacial reaction is rate-limiting up to ca. 1200 °C. Between 1050 and ca. 1350 °C the resistance of pore diffusion becomes the rate determining factor in the Boudouard reaction. Above 1350 °C the rate of reaction is governed by the diffusion of carbon dioxide through the gaseous layers adhering to the coke particles. The corresponding relationships are illustrated in detail in Figure 10.

Carbon conversion r_e in mol m^{-3} s^{-1} may be computed on the basis of the rate constant k_{eff} derived from Figure 10 [19]

$$r_e = \frac{dn_c}{dt} = k_{eff}\left(n^0_{CO_2} - n^{eq}_{CO_2}\right) \tag{2}$$

where $n^0_{CO_2}$ is the CO_2 concentration in the gas phase (mol/cm^3) and $n^{eq}_{CO_2}$ the CO_2 concentration in equilibrium with C and CO (Boudouard reaction).

Furthermore

$$k_{eff} = k_m \cdot m_C \cdot \eta \tag{3}$$

where m_C is the mass of carbon (g) per cubic meter of charge and η the pore utilization factor according to Thiele. Within the temperature range in which the interfacial reaction is rate determining, the rate constant is

$$k_m = H_C \cdot e^{-360/RT}\,g^{-1}s^{-1} \tag{4}$$

where H_C is the reactivity factor. Moreover, because $n = 1$

$$k_{eff} = m_C \cdot H_C \cdot e^{-360/RT}\,s^{-1} \tag{5}$$

The activation energy of 360 kJ/mol is uniformly applicable with respect to any fuel [27]. Depending on reactivity and charge size, the product $m_C \times H_C$ may range from 0.4×10^{13} s^{-1} to 0.4×10^{15} s^{-1}.

Reducing Gas. Assuming that iron oxide is present in the *solid state,* industrial-scale reduction of iron ore with carbon monoxide or hydrogen takes place according to

$$FeO_n + n\,(CO, H_2) \rightarrow Fe + n\,(CO_2, H_2O) \tag{6}$$

If iron oxide is present as a *liquid,* a second reaction is also possible:

$$FeO_n + nC \rightarrow Fe + nCO \quad (7)$$

Carbon monoxide is produced in the blast furnace from the exothermic reaction of oxygen in the hot blast air with hot coke and other reducing agents such as injected coal or oil

$$C + 1/2\,O_2 \rightarrow CO \quad (8)$$

Carbon monoxide is also the product of the endothermic Boudouard reaction of coke or coal carbon with CO_2 in the gas phase

$$C + CO_2 \rightleftharpoons 2\,CO \quad (1)$$

Carbon dioxide required by Equation (1) is formed during the reduction of iron oxide according to Equation (6). In some cases, *coal* is utilized as the reducing agent, which means that the gases actually responsible for reduction arise both from coal pyrolysis and from coal gasification inside the reduction reactor.

Coal pyrolysis may lead to varying quantities of hydrogen and hydrocarbons, which in turn serve partly as reducing agent and partly as energy carrier. The majority of the reducing gas in such a case originates from the solid carbon contained in the coal, where ore reduction and the Boudouard reaction are linked through Equations (1) and (6).

Gaseous reducing agents other than those formed in the reduction reactor itself are derived from natural gas, oil, or coal. Stoichiometrically, the large number of processes that are actually suitable for gas production, is limited significantly because a low content of steam and carbon dioxide as well as a specific hydrogen : carbon monoxide ratio is required in the reducing gas.

An appropriate gas for reduction above the decomposition temperature of carbon monoxide is that produced by steam reforming of natural gas. This gas has a composition of 73 % hydrogen, 13 % carbon monoxide, 1 % water, 8 % carbon dioxide and 5 % methane:

$$CH_4 + H_2O \rightarrow CO + 3\,H_2$$

In the *Midrex process* a 1.5 : 1 ratio of hydrogen and carbon monoxide is required. This ratio is achieved by catalytic reaction of natural gas with the CO_2 of the Midrex top gas in a reformer, which results in a better utilization of input energy:

$$CH_4 + CO_2 \rightarrow 2\,CO + 2\,H_2$$

The reducing gas produced in the reformer has a composition of approximately 56 % H_2, 36 % CO, 3 % CO_2, and 2 % CH_4. Reducing gas should contain as little steam and carbon dioxide as possible. Even relatively small amounts of these substances drastically limit the utility of the gas, because according to Equation (6) the reduction of iron oxide itself produces carbon dioxide and water. Their presence in the reduction gas would therefore shift the equilibrium to the side of iron oxide. At the temperatures normally employed for converting iron oxide to iron, the ratio $CO : CO_2$ or $H_2 : H_2O$ must not fall significantly below 2.3. In addition, reduction gas should contain as little undecomposed hydrocarbons as possible.

Figure 11. Steel industry – trend in specific refractory consumption

The use of fossil reducing agents in iron making is subject to careful reevaluation, and development of new reduction techniques is expected. It is quite likely that coal will come to play an increasingly important role as a source for production of reducing gas (see Section 2.7). This can be accomplished by partially combusting coal with oxygen in an iron bath for the production of hot metal in smelting reduction processes. The resulting hot gas is then used to reduce iron oxide in a separate vessel (see the equations above). Then the reduced iron is itself transferred to the iron bath where it is melted. Gas generation on the basis of nuclear energy is expected to remain economic for many years, although some effort is currently being directed toward the use of a

plasma arc for converting carbon sources into reducing gas.

2.1.3. Refractory Materials [27 – 29]

Refractory materials must meet the following requirements:

1) Mechanical stability under load at high temperatures (up to and beyond 1800 °C, depending on quality),
2) Resistance to slag and dust at high temperature,
3) Specific thermal properties, such as thermal conductivity, specific heat, and resistance to sudden temperature changes, depending on application.

These properties can be tested in the laboratory under conditions similar to the service conditions. Some methods are specified to internationally standards (PRE, i.e., Fédération Européenne de Produits Refractaires and ISO recommended test methods) [27]. Refractories are classified by chemical-mineralogical criteria and by process requirements. The basic distinction is between shaped products (bricks) and unshaped ones (mixtures, mortars, castables). Another basis for classification is the type of binding. Here a distinction must be made between fired products (firing temperatures 800 – 1800 °C) and unfired, chemically bonded refractories (using phosphate binders, resin binders, refractory cements, water glass, magnesium sulfate).

In the iron and steel industry in Germany, the classification of the "Steel and Iron Material Data Sheets" (Stahl – Eisen-Werkstoffblätter) is used [30].

Figure 11 shows the consumption of refractory materials (kg per tonne of crude steel) for the different regions worldwide. The steep decline is mainly accounted for by new steelmaking technologies (oxygen-injection process replacing the Siemens – Martin furnace, introduction of continuous casting) and by improvements in refractory quality [31 – 33].

This trend is also clear from Table 9, which lists the output of the main qualities of refractory bricks in Japan. The 1970 and 2003 figures show the decrease in fireclay brick and silicate brick production and the increase in high-grade refractories (magnesia-carbon, high-alumina castables).

The world steel industry is the principal consumer of refractories (ca. 60 %).

Pig-iron production includes (1) blast furnaces with hot blast stoves, and (2) torpedo ladles, with a molding capacity of 150 – 600 t of molten pig iron, as transport containers from the blast furnace to the steelworks. This sector mainly uses the following refractory qualities: carbon and graphite bricks, silicon carbide bricks, materials containing more than 50 wt % alumina, fireclay, and silica.

In steelworks the most important qualities are magnesia – carbon bricks, bricks and mixtures based on magnesia and dolomite, and high-alumina castables and bricks. Synthetic-alumina-based refractories have become more important. The trend towards high-performance refractories is ongoing due to increasingly severe process conditions.

Blast Furnaces. Molten pig iron and slag are present in the lower part of the blast furnace (bottom and hearth). Repairs cannot be made to this part of the furnace during operation. Chemical and mechanical attacks on the refractory material occur here. Graphite and carbon bricks are the most important structural refractories for this portion of the blast furnace. Carbon bricks have a higher cold-crushing strength than graphite bricks and those containing some graphite (part-graphite and semi-graphite bricks). Carbon bricks have a lower porosity than graphite bricks. Microporous carbon and part graphite bricks with additions of alumina and silicon have a higher resistance to alkali and pig iron [35 – 38].

The current state of the art is the "ceramic cup", which comprises either sintered mullite bricks or high-quality fireclay bricks (48 % Al_2O_3) placed in front of the carbon brick on the bottom, and either large prefabricated panels of corundum concrete or small SiAlON bonded corundum bricks in front of the carbon brick on the wall. This type of lining protects the carbon bricks and prolongs their service life greatly [39, 40]. In the other zones of the blast furnace (bosh, belly, stack), a variety of brick qualities are used. These include bricks containing over 50 wt % alumina, corundum bricks, and silicon carbide bricks with various binders. Hard fire-

clay bricks are usually employed in the stack. For intermediate repairs of the stack, shotcreting materials are used. Here the material is wet mixed, pumped, and sprayed onto the surface of the wall. Furnaces often differ greatly in their refractory linings. The properties of some refractory structural materials are given in Table 10.

Runner and Taphole Mixtures. Tar-free unshaped products containing > 50 % alumina, silicon carbide, and carbon are used in cast, vibrated or rammed form. A large number of very different mixes are in use, including mixtures with spinel ($MgAl_2O_4$)-containing material for use at the metal level and products with up to 80 % SiC at the slag level.

Hot Blast Stoves. The standard lining consists of silica bricks in the dome (temperatures up to 1500 °C), bricks with >50 wt % alumina in the combustion chamber, and silica and fireclay bricks (depending on thermal stress) in the checkerwork shaft. Magnesia bricks have also been tried in place of silica bricks in the upper part of the checkerwork shaft.

Torpedo Ladles [41, 42]. In the lining design, the following factors relating to stresses on the refractory must be considered: temperature of pig iron (1450 – 1520 °C), distance transported, slag composition, and metallurgical reactions such as desiliconization, dephosphorization and desulfurization in the ladle.

Lining bricks mostly contain > 50 % Al_2O_3 (andalusite and bauxite bricks). If the slag has a $CaO : SiO_2$ ratio >1, unfired pitch-bonded dolomite bricks can also be used successfully. The increase in metallurgical reactions in torpedo ladles has led to new types of lining, which have been adopted in an attempt to extend the service life. This can range from 100 000 to 400 000 t pig iron transported. In zone lining,

resin-bonded corundum – carbon – silicon carbide bricks are used in the slag zone (especially in Japan), with resin-bonded andalusite – carbon bricks in the bottom. Linings differ from plant to plant, depending on service conditions.

2.2. Thermodynamic Principles

The following sections deal with the thermodynamic and kinetic principles of ore reduction and serve to provide an understanding of the process technology as well as a critical evaluation of the process with respect to cost effectiveness, product quality, and efficient utilization of the reducing agents.

2.2.1. Thermodynamic Principles of the Reduction Reactions [19, 43, 212]

The principal reactions that occur in the reduction unit are described by

$$\mathrm{FeO}_n \rightarrow \mathrm{Fe} + n\mathrm{O} \tag{9}$$

$$n\mathrm{O} + n\,(\mathrm{C,H_2,CO}) \rightarrow n\,(\mathrm{C,H_2,CO})\,\mathrm{O} \tag{10}$$

Richardson Diagram (Fig. 12). Taking into account that three oxides of iron exist, Equation (9) can be divided into the following steps

$$6\,\mathrm{Fe_2O_3} \rightarrow 4\,\mathrm{Fe_3O_4} + \mathrm{O_2} \tag{11}$$

$$4\,\mathrm{Fe_3O_4} \rightarrow 12\,\mathrm{Fe} + 8\,\mathrm{O_2} \tag{12}$$

$$4\,\mathrm{Fe_3O_4} \rightarrow 12\,\mathrm{FeO} + 2\,\mathrm{O_2} \tag{13}$$

$$12\,\mathrm{FeO} \rightarrow 12\,\mathrm{Fe} + 6\,\mathrm{O_2} \tag{14}$$

The transformation of 6 mol hematite into 12 mol iron requires an elimination of 9 mol O_2 in total. From these, 1/9 is separated between hematite and magnetite, 8/9 between magnetite and iron, 2/9 between magnetite and wustite, and 6/9 between wustite and iron. In other words, 1/3 of the oxygen is separated during the reduction of the higher oxides to wustite and 2/3 during the reduction of wustite to iron.

Oxidation of the reducing agent (Eq. 10) occurs according to the following reactions

$$2\,\mathrm{CO} + \mathrm{O_2} \rightarrow 2\,\mathrm{CO_2} \tag{15}$$

$$2\,\mathrm{C} + \mathrm{O_2} \rightarrow 2\,\mathrm{CO} \tag{16}$$

$$2\,\mathrm{H_2} + \mathrm{O_2} \rightarrow 2\,\mathrm{H_2O} \tag{17}$$

Equations (11) to (14) represent the dissociation reactions of the oxides. Assuming that the activities of the solid phases all equal unity, their equilibrium constants can be represented in the form

$$K_p = p_{\mathrm{O_2}} \tag{18}$$

Whenever the reactants or products are present in the form of liquid or solid solutions, the equilibrium constant of reaction (11), for example, is written as

$$K_p = \frac{a^4_{\mathrm{Fe_3O_4}}}{a^6_{\mathrm{Fe_2O_3}}} p_{\mathrm{O_2}} \tag{19}$$

where a is the thermodynamic activity.

The oxidation of *carbon monoxide* to carbon dioxide is described by Equation (15), the equilibrium constant of which is given by

$$\frac{1}{K_p} = \frac{p^2_{\mathrm{CO}}}{p^2_{\mathrm{CO_2}}} p_{\mathrm{O_2}} \tag{20}$$

Similar expressions are valid for the oxidation of the reducing agents hydrogen and carbon.

For a given temperature the partial pressure of oxygen for reaction (15) is determined by the ratio of carbon monoxide to carbon dioxide (see Eq. 20). The reduction of ore becomes thermodynamically possible by choosing the carbon monoxide : carbon dioxide ratio such that the oxygen partial pressure of the reducing agent is less than the dissociation oxygen pressure of the iron oxide. Similar considerations are valid for hydrogen as the reducing agent.

For *carbon oxidation* the ratio of the partial pressures of oxygen and carbon monoxide depends, for a given temperature, on the total pressure because of a change in the number of moles of the gaseous species during the reaction

$$2\,\mathrm{C} + \mathrm{O_2} \rightarrow 2\,\mathrm{CO}$$

For a given temperature and total pressure the oxygen partial pressure is fixed, provided the gas does not contain other components.

Figure 12. Temperature dependence and oxygen potentials of oxide systems, according to RICHARDSON and JEFFES [43]

The relationship between the free energy of a chemical reaction ΔG and the equilibrium constant K_p is given by

$$\Delta G = -RT \ln K_p \tag{21}$$

Combination with Equation (18) gives the free energy of the dissociation reaction of iron oxide

$$\Delta G = -RT \ln p_{O_2} \tag{22}$$

for the reducing agents the following expressions are valid

$$\Delta G_{CO} = -RT \ln \frac{p^2_{CO_2}}{p^2_{CO}} \cdot \frac{1}{p_{O_2}} \tag{23}$$

$$\Delta G_{H_2} = -RT \ln \frac{p^2_{H_2O}}{p^2_{H_2O}} \cdot \frac{1}{p_{O_2}} \tag{24}$$

$$\Delta G_{C} = -RT \ln p^2_{CO} \cdot \frac{1}{p_{O_2}} \tag{25}$$

Thus, in the case of iron oxides the equilibrium constant depends solely on the oxygen partial pressure. The same holds true for the reducing agents provided the ratios $CO : CO_2$ and $H_2 : H_2O$ are constant. Hence, the expression $-RT \ln K_p$ is called the oxygen potential (unit kJ/mol).

The oxygen potentials of the *dissociation reactions* of the most important oxides and those of the *oxidation reactions* of the reducing agents important in the context of this discussion are shown as a function of temperature in Figure 12 in the form of a Richardson diagram. The scales surrounding the diagram are used to evaluate the value of the oxygen partial pressure, or instead, the respective $CO : CO_2$ and the $H_2 : H_2O$ ratio. The points of the scales have to be connected with point O in the case of oxygen partial pressure, with point C in the case of $CO : CO_2$ ratio,

Figure 13. Phase diagram iron – cementite [43], broken lines refer to the stable system, full lines to the metastable system

and with point H in the case of $H_2 : H_2O$ ratio, respectively. The intersection of these lines with the free energy lines of the single metal – metal oxide system at the temperature of interest yield the equilibrium pO_2, $CO : CO_2$ and $H_2 : H_2O$ ratio of the respective reaction at the selected temperature. Considering for example the $H_2 : H_2O$ ratio, this means that any gas with a $H_2 : H_2O$ ratio in excess of the equilibrium ratio of the selected oxide can be used for reduction and vice versa.

With the aid of this diagram it can easily be determined whether a certain reaction can occur at a given temperature.

For example, iron oxide (FeO) can be reduced with chromium to produce chromic oxide (Cr_2O_3) and iron. On the other hand, silicon dioxide (SiO_2) cannot be reduced with either iron or chromium because at all temperatures the free energy of formation of silicon dioxide is more negative than that of iron oxide or chromic oxide.

It is particularly important that the free energy line pertaining to the reaction

$$2\,C + O_2 \rightarrow 2\,CO \qquad (8)$$

has a negative slope (opposite to that of all dissociation reactions). At temperatures > 1200 °C, the free energy line corresponding to reaction (8) intersects the lines pertaining to chromic oxide and manganese oxide, whereas the line corresponding to silicon dioxide is intersected at 1450 °C. These temperatures may be reached in the lower part of the blast furnace. Thus, it depends on its mode of operation to what extent these oxides are reduced as well.

When considering reduction processes based on carbon, it is important to recognize that the free energy lines of the reactions

$$2\,C + O_2 \rightarrow 2\,CO \qquad (8)$$

$$C + O_2 \rightarrow CO_2 \qquad (26)$$

intersect each other at ca. 700 °C if the pressure is 1 bar. At this point in the diagram $CO : CO_2 = 1$. As can be seen on the free energy line of reaction (8), at higher temperature and 1 bar $CO : CO_2 > 1$, i.e., carbon monoxide formation is favored. At lower temperatures $CO : CO_2 < 1$, i.e., carbon dioxide formation is favored.

To understand the properties of the product formed as a result of the reduction, (hot metal or sponge iron) the iron – cementite (Fe_3C) phase diagram is used (see Fig. 13). As may be seen from the phase diagram, the melting point of iron is lowered from 1540 °C to 1150 °C when 4.3 % carbon is dissolved in the iron. This lowering of the melting point by ca. 400 °C is very important for the blast furnace process. For reduction processes in which solid metallic iron is produced and the reducing agents are carbon or carbon monoxide, the solubility of carbon in α- and γ-iron is important. This control of the carbon content during the refining process subsequent to the reduction step is important to produce the required steel properties. The maximum solubility of carbon in α-iron is 0.03 wt % and 2.1 wt % in γ-iron.

Baur – Glaessner Diagram. This diagram (Fig. 14) may be derived from the Richardson diagram (Fig. 12). In the Baur – Glaessner diagram the stability areas of the iron oxides and iron are depicted as a function of temperature and the composition of the carbon monoxide – carbon dioxide mixtures. For the purpose of an easy evaluation of the process parameters this diagram is preferred to that depicted in Figure 12 because in Figure 14 the gas composition is expressed in volume percent rather than in terms of partial pressure. In addition to the stability areas of the iron oxides the course of the Boudouard reaction

$$2\,CO \rightleftharpoons CO_2 + C \qquad (1)$$

which is obtained by combining Equations (8) and (26) is also indicated in Figure 14. The position of the curve is derived from the data in Figure 12. At low temperature and high concentration carbon monoxide (underneath the Boudouard curve) disproportionates into carbon dioxide and carbon. At high temperature and high concentration carbon dioxide reacts with carbon to produce carbon monoxide.

According to thermodynamic considerations the reduction of iron oxides with carbon monoxide to metallic iron should not be possible below 700 °C (see Fig. 14). Carbon monoxide should disproportionate instead into carbon and carbon dioxide because the free energy of this reaction is higher than that of the reduction reaction FeO + CO → Fe + CO_2. However, nucleation of solid carbon which is necessary for the disproportionation reaction is suppressed. Instead, the reduction reaction is favored and occurs in spite of its lower thermodynamic possibility. Above the Boudouard curve carbon monoxide is regenerated via the reaction of carbon with the carbon dioxide produced in the reduction process. In this region carbon is the final reducing agent. Each formula conversion results in a doubling of the number of moles in the gas phase.

Figure 14. Baur – Glaessner diagram with Boudouard curve [49]

The change in the number of gas molecules as a result of the reaction implies that equilibrium depends on total pressure. The Boudouard curve in Figure 14 is shifted upwards when the pressure is increased.

Lines of equal carbon concentration in γ-iron are also indicated in Figure 14. The curve for the highest carbon concentration corresponds to the saturation boundary ES in the iron – cementite diagram (Fig. 13). On the Boudouard curve in Figure 14 iron is saturated with carbon because the carbon activity, a_C, equals unity on this curve. That is, the carbon content on the Boudouard curve corresponds to the line ES. The carbon content of iron decreases when, for a given temperature, the gas composition corresponding to the Boudouard equilibrium, ($p_{CO,B}$ and $p_{CO_2,B}$) changes into a gas with a lower carbon monoxide content ($p_{CO,l}$ and $p_{CO_2,l}$). The following expression gives the resulting carbon content of the iron, $c_{C,l}$ as obtained from the car-

bon content at saturation, $c_{C,s}$ assuming a constant activity coefficient:

$$c_{C,1} = \frac{p^2_{CO,1}}{p_{CO_2,1}} \frac{p_{CO_2,B}}{p^2_{CO,B}} c_{C,s} \quad (27)$$

Reduction with Gas Mixtures. The extended Baur – Glaessner diagram (Fig. 15) is important for reduction processes based on mixtures of carbon monoxide and hydrogen containing larger or smaller quantities of carbon dioxide and steam. Below 573 °C magnetite is directly reduced to metallic iron. However, the required hydrogen content in the gas mixture in question is higher than the carbon monoxide content. Above 573 °C magnetite is always reduced to wustite. The concentrations of reducing agents in the gas mixture required for the conversion wustite – iron are a function of temperature. The required hydrogen content of the reducing gas decreases with increasing temperature whereas the required carbon monoxide content increases.

Figure 15. Baur – Glaessner diagram for carbon monoxide – carbon dioxide and hydrogen – water vapor mixtures [43]

From a more technological point of view it might be useful to consider only one Baur – Glaessner curve for the four-component gas mixture of CO, H_2, CO_2, and H_2O, and to use the (CO + H_2) or the (CO_2 + H_2O) content as the abscissa of the diagram. Baur – Glaessner curves for this case can be calculated [213]. This is described as follows for the equilibrium curve Fe/FeO.

With the volumetric fraction of the gas components in the mixture denoted by x, the following definitions are introduced:

$$x_{CO_2} + x_{CO} = k_C$$

$$x_{H_2O} + x_{H_2} = k_H$$

$$x_{H_2O} + x_{CO_2} = Y$$

k_C and k_H are the respective total contents of the elements carbon and hydrogen in the gas. Y represents the new abscissa in the Baur – Glaessner diagram. As the mole number does not change during reduction, k_C and k_H are constant for a given reducing gas and independent of the CO : CO_2 or H_2 : H_2O ratio in the gas.

Further:

$$\frac{x_{CO_2}}{x_{CO}} = K_{Fe,CO_2}$$

and

$$\frac{x_{H_2O}}{x_{H_2}} = K_{Fe,H_2O}$$

where K_{Fe,CO_2} and K_{Fe,H_2O} are the respective equilibrium constants for reduction of wustite with CO and H_2 (see Eq. 30). It follows that

$$\frac{x_{CO_2}}{k_C - x_{CO_2}} = K_{Fe,CO_2}$$

and

$$\frac{x_{H_2O}}{k_H - x_{H_2O}} = K_{Fe,H_2O}$$

These two equations are resolved with respect to x_{CO_2} and x_{H_2O}, respectively, and inserted into the above equation for Y

$$Y = k_C \frac{K_{Fe,CO_2}}{1+K_{Fe,CO_2}} + k_H \frac{K_{Fe,H_2O}}{1+K_{Fe,H_2O}}$$

This is the equation for the temperature-dependent Fe : FeO equilibrium curve in the four-component system. The equations for the FeO : Fe_3O_4 and Fe : Fe_3O_4 equilibria are of the same type, only with different equilibrium constants.

Iron – Oxygen Phase Diagram. The stability areas of the various phases are depicted in Figure 16. Information contained in this diagram has been partially incorporated in Figures 12 and 14. In addition, details may be obtained relating to the dissociation of hematite into magnetite and oxygen, the liquid phases that may be formed and the relationships between iron and wustite. It should be stressed that the phases depicted in the phase diagram are not in equilibrium with air but only with an atmosphere of distinct composition, the oxygen partial pressure of which may be obtained from Figure 17. The composition of the reducing gas corresponding to the given oxygen partial pressure may be obtained from the Richardson diagram.

Figure 16. Phase diagram for iron – oxygen, according to DARKEN and GURRY [43]

Lines of equal iron activity are also indicated in Figure 17. The iron activity of the reaction

$$2\,Fe + O_2 \rightarrow 2\,FeO$$

is calculated from the oxygen potential obtained from the Richardson diagram

$$RT \ln K_{FeO,O_2} = RT \ln \frac{a_{FeO}^2}{a_{Fe}^2 \cdot p_{O_2}} \tag{28}$$

assuming $a_{FeO} = 1$.

Figure 17. Oxygen pressure in equilibrium with iron and its oxides as a function of temperature, according to DARKEN and GURRY [43]

Reduction of Oxides in Solid Solution. As already mentioned (see Eqs. 19 and 28), the oxygen partial pressure p_{O_2} depends on the activities of the solid phases. In stable mixed oxides the activities of the iron oxides are less than unity. For example, if iron oxide (FeO) is to be reduced to iron from fayalite ($2\,FeO \cdot SiO_2$), then $a_{FeO} < 1$ in Equation (28). Thus, p_{O_2} is smaller than for the reduction of pure iron oxide. Hence, the carbon monoxide content of the reducing gas used for the reduction of fayalite must be higher than that of the gas used for the reduction of wustite, as may be seen from Equation (20a).

$$p_{O_2} = \frac{1}{K_p} \left(\frac{p_{CO_2}}{p_{CO}} \right)^2 \tag{20a}$$

Similar considerations apply to hydrogen – steam mixtures.

The thermodynamic relationships of the reduction of mixed oxides have not yet been studied as extensively as those pertaining to the pure oxides. Thus a Richardson diagram cannot be presented for the reduction of mixed oxides.

For industrial reduction processes the interactions of silicon dioxide and calcium oxide with the iron oxides are important. The solid phases expected to be formed during reduction and the minimum carbon monoxide content of the reducing gas that is required to produce metallic

iron are shown in Figures 18 and 19. Examples of the possible reduction paths are presented in the diagrams.

Figure 18. System Fe – Fe_2O_3– SiO_2 at 900 °C, showing examples of reduction paths [43]

Figure 19. System Fe – Fe_2O_3 – CaO at 900 °C, showing example of reduction path [43]

Thermodynamic Considerations Concerning the Extraction Processes. From a thermodynamic viewpoint control of the oxygen potential inside the reactor is the only requirement to ensure that the reactions to produce iron and steel proceed. This requirement is more than fulfilled in the blast furnace, because except iron, also silicon, manganese, and phosphorus are reduced to a small degree, and the produced liquid iron also dissolves carbon until the limit of saturation. The oxygen potential of the hot metal is, therefore, much lower than required for iron production alone. In the subsequent oxygen converter, the accompanying elements in the hot metal must be separated by oxidation for the production of steel. The crude steel itself has finally, to be deoxidized. On the way from ore to steel, the attained final oxygen potential is thus, first falling below and then, increasing above the desired value. This circumstance has led to proposed processes in which this circuitous path is avoided. Two alternatives are depicted in Figure 20.

Figure 20. Representation of some reduction processes on the iron – iron oxide and iron – cementite phase diagrams [45]

The iron – iron oxide and iron – cementite phase diagrams, sharing a common temperature axis, are shown in Figure 20. The curve ABCD represents the conventional path to produce steel. AB is reduction to iron, BC carbon dissolution, and CD separation of carbon – and other accompanying elements, which is not shown here – in the oxygen converter. Alterna-

tives avoiding a too strong reduction as in the blast furnace are also shown. The path ABD represents, in principle, the reduction sequence in the direct reduction processes. The oxide oxygen is removed from the solid phase to low residual levels while the temperature increases (point B). Subsequently, the reduced material is melted (curve BD) and refined to steel. The curve AED represents a processing sequence firstly proposed by Ketorp [45], presently known as smelting reduction. According to this sequence, the oxide is melted and in the liquid state reduced with carbon until the system reaches the two-liquid region. Here, iron containing ca. 0.1 % oxygen but no carbon, silicon, phosphorus, or manganese is in equilibrium with a liquid slag still containing a few percent of iron oxide. After separation of the liquid iron, the content of dissolved oxygen is decreased by means of carbon or metallic deoxidizers.

Thermodynamic Boundary Conditions of the Reduction Stoichiometry. It follows from the discussion of the thermodynamic principles that the stoichiometric boundary conditions which determine the mass balances pertaining to the reduction processes, differ from those based on the simple reaction

$$FeO_n + n\,CO \rightarrow Fe + n\,CO_2 \tag{6}$$

In addition, the mass balances are more complicated as a result of the existence of the three oxides of iron.

For example, by making use of the Baur – Glaessner diagram (Fig. 15) it is found that the reaction

$$FeO + 3\,CO \rightarrow Fe + 2\,CO + CO_2 \tag{6a}$$

describing the reduction of wustite with carbon monoxide at the usual reduction temperature of 900 °C, can proceed only until a carbon dioxide content of 31 % in the $CO - CO_2$ gas mixture, as at this content the equilibrium

$$K_{FeO} = \sqrt{\frac{K_P}{K_{FeO,O_2}}} = \frac{p_{CO_2}}{p_{CO}} \tag{29}$$

(see Eqs. 20 and 28 with a_{Fe} and a_{FeO} = 1) is attained. That means that only a little less than one-third of the total amount of CO can be utilized. The remaining gas can, however, be used to reduce Fe_2O_3 to FeO, if the process is carried out in countercurrent flow, i.e., if carbon monoxide or – in the case of the blast furnace – a carbon monoxide – nitrogen mixture is directed upwards from bottom to top through a burden of iron oxide in a shaft. Under these conditions FeO is reduced to Fe in the lower part and Fe_2O_3 is reduced to FeO in the upper part of the burden. The reduction of Fe_2O_3 via Fe_3O_4 to FeO is not restricted by thermodynamic limits because the CO_2 content in the $CO_2 - CO$ mixture in equilibrium with Fe_3O_4 is 82 % at 900 °C and 74 % at 700 °C and in equilibrium with Fe_2O_3 is 100 % (see Fig. 15). According to the 100 % CO_2 in equilibrium with Fe_2O_3, a separate equilibrium line for this oxide is not shown. The amount of oxygen separated from 1 mol iron in the hematite – wustite reduction stage is half of that separated from the iron in the wustite – iron reduction stage (see Section page 33). Since the maximum possible carbon monoxide utilization at FeO reduction is 31 % at 900 °C due to the aforementioned thermodynamic condition, a further amount of $\frac{1}{2} \cdot 31\,\%$ = 15.5 % carbon monoxide can be utilized in the hematite → magnetite → wustite reduction stage. The total possible utilization is, therefore 31 + 15.5 = 46.5 %. This is the theoretical optimum if equilibrium is attained. The same considerations hold principally if $CO - H_2$ mixtures are used. Only the equilibrium gas composition is different and depends on the $CO : H_2$ ratio (see Fig. 15 and following text).

The described restrictions also hold when iron oxide is completely reduced by gas as it is the case in the direct reduction processes which use natural gas as the primary energy source (see Section 2.6). The off-gas of these processes consisting of a $CO - H_2 - CO_2 - H_2O$ gas mixture may, however, be used partially for combustion in order to supply the heat for the endothermic conversion of natural gas into the reducing gas ($CO + H_2$), and partially for the reforming reaction itself:

$$CH_4 + CO_2 \rightarrow 2\,CO + H_2$$

and

$$CH_4 + H_2O \rightarrow CO + 2\,H_2$$

The total gas utilization in that process type is, therefore, high.

If carbon is the primary fuel for the reduction process as for example in the blast furnace,

the gas utilization may be improved above that of pure gas reduction processes, because part on the wustite is reduced by the so-called direct reduction:

$$FeO + C \rightarrow Fe + CO \quad \text{(Eq. 7 with } n = 1\text{)}$$

This decreases the carbon monoxide volume per mole of iron required for reduction of the remaining wustite according to Equation (6a). Moreover, the percentage of carbon monoxide required for reduction of the higher oxides increases above one-third of the entire requirement, and hence, gas utilization rises (for details see Section 2.2.2).

2.2.2. Mass and Heat Exchanges of the Reduction Reaction with Carbon as the Primary Fuel

Two-Stage Reduction. The most important primary energy source for iron oxide reduction is coal. The following considerations are thus restricted to carbon, in order to simplify the fundamental relations. The reduction reaction itself proceeds always with gas, as only a gas can contact the entire – outer and inner – surface of the ore, and hence, enables the fastest reduction. The reduction gas carbon monoxide is produced by gasification of carbon. Gasification proceeds entirely or partially according to the Boudouard reaction (Eq. 1). Together with gas reduction (Eq. 6a) it yields the direct reduction reaction:

$C + CO_2 \rightarrow 2\,CO$	Boudouard reaction	(1)
$CO + FeO \rightarrow CO_2 + Fe$	Reduction reaction	(6a)
$C + FeO \rightarrow CO + Fe$	Direct reduction	(30)

Direct reduction is carried out at temperatures $> 800\ ^\circ C$, usually at ca. 1200 °C, because at this temperature the Boudouard equilibrium lies on the CO side and the product of direct reduction is iron, saturated with liquid carbon.

Carbon monoxide produced by the direct reduction reaction can be used to reduce further amounts of iron oxide according to Equation (6a), as mentioned. Therefore, reduction with coal is usually carried out in two stages, namely direct reduction above 800 °C and prereduction or indirect reduction, below 800 °C. This temperature can vary in a certain range depending on the coal reactivity.

Direct reduction is a strongly endothermic process due to the endothermic character of the Boudouard reaction, whereas indirect reduction is weakly exothermic. For this reason the two-stage reduction with coal needs supply of heat. This is possible in principally three ways:

1) Combustion of an additional amount of carbon with oxygen (or air) to carbon monoxide
2) Post-combustion of carbon monoxide to carbon dioxide
3) Supply of electrical energy

Combustion of an Additional Amount of Carbon with Oxygen (or Air) to Carbon Monoxide. This method is the most important. It is applied in the blast furnace and in smelting reduction processes.

The combustion of additional carbon with oxygen (or air) gives a certain amount of carbon monoxide as the combustion product. This amount together with the carbon monoxide generated by the direct reduction reaction gives a total amount of carbon monoxide which is then used for reduction of the remaining FeO and the higher oxides Fe_3O_4 and Fe_2O_3 in the prereduction stage. The total amount of produced carbon monoxide per tonne of iron must be the same as that consumed in the prereduction stage. In the blast furnace this occurs automatically because both stages are united within one process. In two-stage prereduction and smelting reduction processes this condition must be fulfilled in order to obtain the optimum operating point of the process in total. Figure 21 [214] shows this for the case that direct reduction is carried out with pure carbon and oxygen as the combustion medium; and that prereduction proceeds in a countercurrent shaft under the condition that equilibrium is attained at the position in the shaft where FeO reduction starts. The respective volumes of carbon monoxide consumption and production per tonne of iron are plotted against the degree of prereduction. Production and consumption are equal where the lines intersect. This is the case at 74 % prereduction. The point designates optimum operating conditions and at the same time the limit between the prereduction and the smelting reduction stage of the process. In the upper part of the figure, the carbon monoxide utilization at the end of reduction, i.e., at the top of the prereduction shaft, is shown.

Figure 21. Optimum prereduction degree of a combined pre- and smelting reduction process with carbon. Prereduction at 900 °C [214]

The lowest utilization occurs if prereduction is 100 %, i.e., if the FeO is entirely reduced in the shaft. If FeO is partially reduced in the smelting reduction stage, gas utilization improves. Below prereduction degrees of 43 % gas utilization is 100 %, i.e., the off-gas consists to 100 % of CO_2. But in this case less gas would be required for prereduction than is actually generated in the smelting reduction stage at this degree of prereduction. The process is no longer balanced and excess carbon monoxide is generated. The way to overcome this difficulty is smelting reduction with application of post-combustion.

Post-combustion. Post-combustion of carbon monoxide to carbon dioxide and transfer of the thus generated heat to the direct reduction stage is the second method to balance the heat requirements in the direct reduction stage.

This method has been used for a long time in the rotary kiln direct reduction process [215]. Post-combustion with oxygen is also used in smelting reduction processes [216] (see page 137). The carbon monoxide, generated from the direct reduction reaction (30) is post-combusted above the melt with oxygen blown in from the top, and the combustion heat is transferred back to the melt. Instead by combustion of additional carbon to carbon monoxide, the heat requirement for direct reduction is supplied here by combustion of the produced carbon monoxide to carbon dioxide

$$CO + \frac{1}{2}\,O_2 \rightarrow CO_2$$

By this method the total enthalpy of CO_2 formation from carbon and oxygen is released, while in the first case it is only the enthalpy of CO formation. Therefore, carbon consumption decreases and hence, the amount of gas per tonne of iron produced in the smelting reduction stage. As a consequence, the intersection point of the curves of gas production and gas consumption in Figure 21 is shifted to lower prereduction degrees and gas utilization becomes higher. However, this advantage can only be exploited, if the post-combusted gas produced in the smelting reduction stage consists exclusively of carbon monoxide. Otherwise, the known thermodynamic limit prevents the reduction of wustite

to iron. It follows, that the CO_2 part in the post-combusted gas must be washed out before the gas enters the prereduction stage. The situation changes, when instead of wustite magnetite and hematite are reduced in the prereduction stage, i.e., if the prereduction degree is below 35 %. The thermodynamic limit of 33 % CO_2 in the CO – CO_2 mixture valid for the wustite – iron equilibrium at 800 °C vanishes, and only the limit of the magnetite – wustite equilibrium (76 % CO_2 in the CO – CO_2 mixture at 800 °C) remains (see Fig. 14). The degree of post-combustion must be ca. 52 % to cover the heat demand for smelting reduction of the 35 % prereduced ore. Since 52 % CO_2 is less than 76 % CO_2, that gas is able to reduce magnetite without CO_2 washing. Gas utilization at the top of the prereduction stage is 82 % in that case. That means an almost complete gas utilization and a correspondingly low fuel consumption can be attained by this operation.

Electrical Energy as the Heat Supplier. If electrical energy supplies the demand of heat for direct reduction, carbon is only consumed for the direct reduction reaction. No carbon combustion for heat generation as in the blast furnace is required. Carbon consumption and the corresponding gas production is, therefore, less than in the blast furnace. This way of operation was practiced in the so-called Plasmamelt process [217] (see Section 2.7.1).

Rist Diagram. The Rist diagram (see Fig. 22) is a useful tool for the evaluation of the complex problems related to the subject of mass balances and thermodynamic limits [218]. For a given reduction process, the diagram shows the exchange of oxygen between iron oxide and the reducing agent. The degree of oxidation of carbon is indicated on the abscissa by the molar ratio oxygen : carbon. The positive part of the ordinate gives the degree of oxidation of iron in terms of the molar ratio oxygen : iron. Here hematite is represented by $FeO_{1.5}$, magnetite by $FeO_{1.33}$ and wustite by $FeO_{1.05}$. The negative part of the ordinate indicates the molar ratio of oxygen from other sources to iron. In the blast furnace such "other source" is, for example, the hot blast used for the oxidation of coke, in smelting reduction processes it is the oxygen blown in for combustion of carbon to carbon monoxide.

Figure 22. Representation of various reduction processes in the Rist diagram [45]

The blast furnace process is represented by the line FA in Figure 22. The oxidation of carbon to produce the process heat is represented by GH, carbon is oxidized from S to G. The section FG represents the reduction of oxides such as SiO_2 and MnO.

The direct reduction of iron oxide takes place on the section HK, after which carbon is completely oxidized to carbon monoxide. Indirect reduction proceeds along the line KA which touches point W (wustite) whenever the gas utilization is optimum. Point A is then located about halfway between O/C = 1 and O/C = 2, corresponding to a gas utilization of 50 %. In practice the gas utilization is closer to 40 %. The line FA is then steeper and no longer touches point W.

The slope (C/Fe) of a process line in the Rist diagram is an indication of the specific carbon or reducing agent demand of the process. For the blast furnace process the specific carbon demand is ca. 1.9 mol carbon per mole of iron.

The process represented by the line CC' is the rotary kiln direct reduction process, here for the case of hematite reduction. As no carbon is oxidized as a heat supplier before reduction and no SiO_2 and MnO, etc., is reduced, the line starts at point C. About 75 % of the iron is reduced by direct reduction (line CL). A CO – CO_2 mixture with 80 % CO leaves the charge and is combusted to 100 % CO_2 (point C'). The heat released from this oxidation satisfies the energy requirement of the reduction reaction. According to the degree of direct reduction, the specific carbon demand is 0.8 – 1.5 mol carbon per mole of iron for hematite and 0.8 – 1.33 mol carbon per mole of iron for magnetite. The line CN represents the case if the heat for direct reduction is supplied by electrical energy. Gas utilization is limited to 82 % because the curve contacts the wustite – iron equilibrium point W. The portion of direct reduction is somewhat higher than 50 %. Reduction of SiO_2 and MnO is not considered. Line ELMN presents the case of a combined pre- and smelting reduction process with 52 % post-combustion of the off-gas from the smelting reduction reactor. Section LM represents the post-combustion process. Prereduction is 25 %, gas utilization 82 %. It is assumed in Figure 22 that no oxygen is employed for the combustion of carbon to carbon monoxide. Heat is supplied only by the post-combustion reaction. In practice, usually part of the oxygen blown in is used for the combustion of carbon to carbon monoxide. Line 0B describes a process with 100 % reduction by gas according to

$$3\ (CO+H_2) + Fe_2O_3 \rightarrow 3\ (CO_2+H_2O) + Fe$$

Because of the wustite – iron equilibrium, gas utilization is low here.

2.2.3. Thermodynamic Principles of Metal – Slag Reactions [43, 46]

In reduction processes in which liquid iron is produced the slag plays an important role. It should

1) absorb those components contained in the raw material that are undesirable in iron,
2) be easily separable from the metal because of its low viscosity, low density and the low vapor pressure of its components,
3) be largely inert with respect to refractory materials although the slag consists primarily of metal oxides like many refractory substances,
4) have properties suitable to make it a saleable product.

Individual Reactions. The most important metal – slag reactions discussed here are:

$$(FeO) \rightleftharpoons [Fe] + [O] \tag{31}$$

$$(SiO_2) \rightleftharpoons [Si] + 2\,[O] \tag{25}$$

$$(MnO) \rightleftharpoons [Mn] + [O] \tag{33}$$

$$(3\,CaO{\cdot}P_2O_5) \rightleftharpoons 3\,(CaO) + 2\,[P] + 5\,[O] \tag{34}$$

$$[S] + (CaO) \rightleftharpoons (CaS) + [O] \tag{35}$$

$$[C] + [O] \rightleftharpoons \{CO\} \tag{36}$$

(Round brackets refer to the slag phase, square brackets to the metal phase and curly brackets to the gaseous phase.)

The equilibrium of each of these six reactions depends on the oxygen activity in the metal bath. The oxygen activity in the lower part of the blast furnace – for which these considerations are valid – is for all practical purposes constant to the extent that equilibrium is established. The oxygen activity in this equilibrium is, however, much higher than its activity in the equilibrium of reaction (36). This is easily to understand if it is taken into account that the reduction reactions (31) – (35) with coke (according to Eq. 36) start with high oxygen potential in the initially FeO rich slag while liquid metal and slag flow down through the burden of solid coke. The reactions cease when the liquid phases come below the plane of the tuyeres, since below that plane no gas phase exists any more. The absence of the gas phase prevents a further progress of reaction (36), and thus, the oxygen activity becomes constant. Equilibrium with carbon and carbon monoxide is not yet attained. In the hearth no more than exchanges among reactions (31) –

(35) are possible until the slag – metal equilibrium with all the slag and metal components and with one constant oxygen activity is established.

The free enthalpies of formation for the reactions (31) – (36) are expressed as follows:

$$-\Delta G_{FeO} = RT \ln \frac{a_{[Fe]}}{a_{(FeO)}} a_{[O]}$$

$$-\frac{1}{2}\Delta G_{SiO_2} = RT \ln \frac{a_{[Si]}}{a_{(SiO_2)}^{1/2}} a_{[O]}$$

$$-\Delta G_{MnO} = RT \ln \frac{a_{[Mn]}}{a_{(MnO)}} a_{[O]}$$

$$-\frac{1}{5}\Delta G_{3\,CaO\cdot P_2O_5} = RT \ln \frac{a_{(CaO)}^{3/5} a_{[P]}^{2/5}}{a_{(3\,CaO\cdot P_2O_5)}} a_{[O]}$$

$$-\Delta G_{CaS} = RT \ln \frac{a_{(CaS)}}{a_{(CaO)} a_{[S]}} a_{[O]}$$

$$-\Delta G_{CO} = RT \ln \frac{a_{[C]}}{p_{CO}} a_{[O]}$$

From these equations it can be derived that the reduction of components less noble than iron (Mn, Si, and P) into the hot metal, is enhanced as long as their activities in the metal phase are much lower than unity. Sulfur is mainly taken up by the slag as long as the slag has a high activity of CaO and the oxygen activity $a_{[O]}$ is low. Besides the above-mentioned elements, reduction of lime and alumina as important slag components is also possible in principal. However, their free enthalpies of formation are so large, that Ca and Al contents present in the hot metal remain below the limit of analytical proof. Thus, these reduction reactions can be neglected.

When considering reactions (31) to (36) individually the following should be noted.

Equation (31): For a given temperature the equilibrium *(FeO)-content of the slag* depends on the activity of iron oxide that, in turn, depends on the other slag components. This occurs because the iron activity in the hot metal equals unity while the oxygen content [O] is also fixed. Since the line $2\,Fe + O_2 \rightleftharpoons 2\,FeO$ in the Richardson diagram lies well above the line $2\,C + O_2 \rightleftharpoons 2\,CO$, the iron oxide reduction equilibrium is shifted to the far right, resulting in low (FeO)-contents in the slag.

Equation (32): The *reduction of silica* is of particular interest when discussing metal – slag reactions. This reaction is very sensitive to changes in temperature and, hence, the oxygen potential, as may be seen from the Richardson diagram. The extent of the silica reduction is used to judge the extent to which the other reactions have proceeded. This is a consequence of the circumstance that the silicon equilibrium is neither shifted entirely to the silicon [Si] side nor entirely to the silicon dioxide (SiO_2) side and because the (SiO_2) contents of the slag are certainly high, but SiO_2 is only weakly reduced due to its high free energy of formation. Silicon contents are usually above 0.2 % and mostly below 1 %, and in this range can easily and precisely be determined by the usual analytical methods. For blast furnace control purposes the [Si] and (SiO_2) contents represent important control quantities that describe the conditions in the lower part of the furnace.

Equation (33): The conditions that determine the *manganese content* [Mn] of the hot metal follow from considerations similar to those that determine the silicon content. However, under the conditions prevailing in the blast furnace the manganese equilibrium is shifted more to the metal side, because manganese is more noble than silicon, as may be seen from the Richardson diagram.

Equation (34): The *reduction of apatite* is complete and phosphorus is transferred entirely to the hot metal.

Equation (35): Because the *sulfur content* of the hot metal should be as low as possible, it is desirable that the reaction proceed in the direction of calcium sulfide (CaS) formation. The desulfurization increases with increasing lime activity in the slag and sulfur activity in the hot metal and with decreasing calcium sulfide activity in the slag and oxygen activity in the hot metal.

Equation (36): It is necessary that the reduction reaction with carbon proceeds to a certain degree in the stack of the blast furnace in order to attain sufficiently low oxygen activities in the hot metal for good desulfurization of hot metal. This is mainly achieved by temperature adjustment. High temperature favors the reducing capability of carbon according to equation (36) as can be derived from the Richardson diagram.

Equilibria. The equilibria of the aforementioned reactions are related to one another by the constant oxygen activity $a_{[O]}$. In order to handle the equilibria practically, it is useful to express the activities by the products of concentrations

and the activity coefficients. As far as the metal phase is concerned, the activity coefficients of its components are almost constant over the entire range of concentration, because at the low actual concentrations, the thermodynamic interrelation between the single elements can be neglected, which means that Henry's law is valid. This is not the case with carbon, but for this element $a_{[C]} \cong 1$ can be assumed as an approximation. The activity coefficients of the slag are strongly concentration dependent. For a current production run, however, the slag composition changes very little so that the activity coefficients are also constant. It must be taken into account, however, that with every change of slag composition the activity coefficients change. For blast furnace type slags a good documentation of slag activities exists [63]. Making use of the concept of activity coefficients in the case of the slag components and using concentrations instead of activities for the metal components except carbon, the following equilibrium constants can be written:

1) For the reduction of silica

$$K^*_{\mathrm{Si}} = \frac{[\mathrm{Si}][\mathrm{O}]^2}{f_{\mathrm{SiO_2}}(\mathrm{SiO_2})} \text{ or :} \qquad K^*_{\mathrm{Si}} \cdot f_{\mathrm{SiO_2}} = \frac{[\mathrm{Si}][\mathrm{O}]^2}{(\mathrm{SiO_2})} = K_{\mathrm{Si}} \tag{37}$$

2) For the desulfurization reaction

$$K^*_{\mathrm{S}} = \frac{[\mathrm{S}]}{(\mathrm{S})} \cdot \frac{f_{\mathrm{CaO}}(\mathrm{CaO})}{[\mathrm{O}]} \text{ or :} \qquad \frac{K^*_{\mathrm{S}}}{f_{\mathrm{CaO}}} = \frac{[\mathrm{S}]}{(\mathrm{S})} \cdot \frac{(\mathrm{CaO})}{(\mathrm{O})} = K_{\mathrm{S}} \tag{38}$$

3) For the reduction of manganese oxide

$$K^*_{\mathrm{Mn}} = \frac{[\mathrm{Mn}]}{f_{\mathrm{MnO}}(\mathrm{MnO})}[\mathrm{O}] \text{ or :} \qquad K^*_{\mathrm{Mn}} \cdot f_{\mathrm{MnO}} = \frac{[\mathrm{Mn}]}{(\mathrm{MnO})}[\mathrm{O}] = K_{\mathrm{Mn}} \tag{39}$$

The oxygen concentration in the equilibria (37), (38), and (39) is the same. Therefore, each two of the three equations can be combined by eliminating the oxygen concentration. Including the approximately constant SiO_2 and CaO contents of the slag in the constants and exchanging (MnO) for (Mn) then yields:

$$\frac{1}{K^{1/2}_{\mathrm{Si}} \cdot K_{\mathrm{S}}} \cdot \frac{(\mathrm{CaO})}{(\mathrm{SiO_2})^{1/2}} = K_{\mathrm{Si,S}} = \frac{1}{[\mathrm{Si}]^{1/2}} \cdot \frac{(\mathrm{S})}{[\mathrm{S}]} \tag{40}$$

$$\frac{K^{1/2}_{\mathrm{Si}}}{K_{\mathrm{Mn}}}(\mathrm{SiO_2})^{1/2} = K_{\mathrm{Si,Mn}} = [\mathrm{Si}]^{1/2} \cdot \frac{(\mathrm{Mn})}{[\mathrm{Mn}]} \tag{41}$$

$$\frac{(\mathrm{CaO})}{K_{\mathrm{Mn}} \cdot K_{\mathrm{S}}} = K_{\mathrm{Mn,S}} = \frac{(\mathrm{S})}{[\mathrm{S}]} \cdot \frac{(\mathrm{Mn})}{[\mathrm{Mn}]} \tag{42}$$

The three constants are approximate values that describe the relations between the silicon reduction, the manganese reduction, and the desulfurization reaction. They were introduced by Oelsen and coworkers [47]. The values of these constants are mainly dependent on the slag composition [47] especially the so-called basicity, but otherwise comparatively constant. Thus, they proved as a useful tool to predict the behavior of the blast furnace.

All the aforementioned constants depend on the slag basicity. The basicity is the ratio between the sum of the basic slag components and the sum of the acid components. Because the effect of various basic oxides on the basicity is different, their concentrations are expressed in terms of equivalent concentrations by making use of an equivalency factor; the latter equals unity for calcium oxide. Similar factors are used for the acid components in which case silica is the reference oxide.

The basicity B may be expressed by a series of complicated expressions [43], as well as by equations depending on accuracy and range of B required

$$B = \frac{(\%\mathrm{CaO}) + (\%\mathrm{MgO})}{(\%\mathrm{SiO_2}) + (\%\mathrm{Al_2O_3})} \tag{43}$$

or

$$B = \frac{(\%\mathrm{CaO}) + 0.7\,(\%\mathrm{MgO})}{0.93\,(\%\mathrm{SiO_2}) + 0.18\,(\%\mathrm{Al_2O_3})} \tag{44}$$

and, finally, when neglecting low magnesia and alumina contents

$$B = \frac{(\%\mathrm{CaO})}{(\%\mathrm{SiO_2})} \tag{45}$$

The constants $K^*_{\mathrm{Si,S}}$, $K_{\mathrm{Mn,Si}}$ and $K_{\mathrm{Fe,Si}}$ are shown in Figure 23 as a function of the basicity and for various alumina contents. $K^*_{\mathrm{Si,S}}$ is the reciprocal value of $K_{\mathrm{Si,S}}$ and $K_{\mathrm{Fe,Si}}$ is the constant that describes the reduction of iron oxide from the slag. It is seen from the diagram that, for a given basicity, the constants are hardly affected by the replacement of calcium oxide by magnesium oxide.

Activities. On the basis of many laboratory and blast furnace plant experiments it has been

Figure 23. Equilibrium constants $K_{\mathrm{Mn,Si}}$, $K_{\mathrm{Fe,Si}}$ and $K^*_{\mathrm{Si,S}}$ as a function of the basicity (CaO + MgO)/(SiO_2) with the Al_2O_3 content and the MgO/CaO ratio as parameters [47]
(MgO)/(CaO):

(z) = slightly viscous liquid; d = heavy viscous liquid

established that the metal : slag distribution ratios can be accurately evaluated with the aforementioned constants. To obtain a better insight into the basic interactions between the various components in the metal and the slag, information is needed concerning their activities and how these are affected. In general, the relation between the concentration of a component and its activity a is characterized by the activity coefficient f. Whenever the activity is affected by other components, which also form a dilute solution with the solvent, the activity coefficient is denoted by $f^{\,x}$. The activity of sulfur is given by

$$a_{\mathrm{S}} = f^x_{\mathrm{S}}\,[\mathrm{S}] \tag{46}$$

The values of f^x_{S} may be obtained from Figure 24. The influence of carbon and silicon on the sulfur activity is extremely pronounced. Because their concentrations in the hot metal are relatively high, the sulfur activity is increased, facilitating desulfurization.

Figure 24. Activity coefficient of sulfur as a function of the concentration of other solutes [43]
——— Values after CHIPMAN; - - - - - - - Values after SCHENCK

To represent the sulfur activity in hot metal, it is useful to express the effect of all the other

solutes in terms of an *equivalent carbon content* Δc_C. The activity coefficient of sulfur can then be depicted as a function of the carbon content with the silicon content as the parameter (see Fig. 25). With the aid of this diagram it is easy to evaluate the activity coefficient of sulfur $f_S^{(Si,C)}$, important in the production of hot metal, at various temperatures. The carbon content c_C in Figure 25 is obtained from the actual carbon content $c_{C,t}$ as follows:

$$c_C = c_{C,t} + \Delta c_C \quad (47)$$

with

$$\Delta c_C = 0.043\% \, [P] - 0.025\% \, [Mn] - 0.028\% \, [S] \quad (48)$$

At equilibrium the chemical potential of sulfur in the metal and the slag is equal. The sulfur in the slag is present as calcium sulfide (CaS) for the oxygen potential prevailing inside the blast furnace. The solubility limit of calcium sulfide in lime – silica slags is ca. 2 % sulfur. Hence, the sulfur activity in the slag reaches its maximum value at these low sulfur contents. The activity is shown in Figure 26 as a function of the sulfur content of lime – silica slags with the basicity B as the parameter.

Figure 25. Activity coefficient of sulfur as a function of the carbon content [43] (isotherms for 1200 to 1600 °C)

Figure 26. Activity of calcium sulfide as a function of the sulfur content of lime – silica slags with the basicity B as the parameter [43]

Phase Diagrams. Essentially, blast furnace slags contain four components: calcium oxide, silicon dioxide, magnesium oxide, and aluminum oxide. However, ternary systems are easier to visualize and for this reason blast furnace slags are frequently represented by a quasi-ternary section of the $CaO - SiO_2 - MgO - Al_2O_3$ diagram at a constant alumina content of, for example, 10 % which is typical for blast furnace slags (Fig. 27). This type of representation is useful because the alumina content is essentially determined by the gangue constituents of the ore and, hence, remains constant. The magnesia content, on the other hand, changes with changing dolomite additions to the burden.

2.3. Kinetic Principles [19, 43, 48, 212]

In the reduction processes which are commercially important at present, reduction in the solid and in the liquid state can be distinguished. Both processes are heterogeneous reactions between several phases. Knowledge of the reduction in the solid state is rather extended, whereas that on reduction in the liquid stage is still meager.

2.3.1. Reduction in the Solid State

During reduction in the solid state, the gas composition is generally a function of space and

Figure 27. Phase relationships and liquidus temperatures in the system CaO – MgO – SiO_2 – Al_2O_3 containing 10 % Al_2O_3 [46]

time within the ore particle, and depends on the overall location in the *continuous reactor*. In a *batch reactor* the gas composition is also time dependent. The number, spatial arrangement, structure, and chemical composition of the solid phases change as the reduction progresses. The time dependencies of the various stages that constitute the reduction process are known. Three distinct phenomena have to be recognized:

1) Reducing gas components (CO, H_2) are transported to the solid oxide phase via *transport phenomena,* the oxidized gas components (CO_2, H_2O) are transported away from the reaction front.
2) The reduction reaction itself proceeds essentially at the *phase boundary* between gas and solid oxide.
3) As a result of the *removal of oxygen* from the surface of the solid phases and the accompanying transport phenomena, new solid phases such as lower iron oxides or metallic iron are being formed.

2.3.1.1. Time Dependence of Individual Processes During Reduction

The overall reduction process is characterized by a series of individual processes representing various resistances to the overall reaction rate. The potential difference that drives the reduction process causes matter to flow through the resistances which are usually in series with each other. Hence, the major portion of the potential difference is expended at the region of highest resistance. Generally spoken the higher the single resistance, the more rate determining it is for the entire process. Because the resistances corresponding to the various mechanisms change according to the choice of the experimental conditions and with the type of ore, the single resistances may be differently distributed over the locations of the ore. For a long time this circumstance was not properly recognized and, consequently, has led to contrasting opinions concerning the reaction step that determines the overall reaction rate. It was not until the 1960s that these phenomena were summarized and clearly presented [19, 212]

Fundamentals. The individual mechanisms important for the reduction kinetics are best described with a model (see Fig. 28). For a discussion of the fundamental laws a partial knowledge of the model is a prerequisite.

Kinetic reaction steps are described with flux equations. A flux equation expresses the fact that a flux (mol m^2 s^{-1}) is caused by a concentration difference as the driving force and related to it by a flux coefficient. Transport phenomena are primarily expressed by Fick's first law

$$j = -D\,\frac{\mathrm{d}c}{\mathrm{d}x} \tag{49}$$

and Fick's second law

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(D\,\frac{\partial c}{\partial x}\right) = D\,\frac{\partial^2 c}{\partial x^2} \tag{50}$$

If the concentration field is independent of time, the gradient dc/dx in Equation (49) can be exchanged by

$$-\frac{\mathrm{d}c}{\mathrm{d}x} = \frac{c_2 - c_1}{\delta} \tag{51}$$

with $c_2 > c_1$. The quantities c_2 and c_1 are concentration values at fixed points, for example at a point of the inner surface of the ore and a point at the outer surface; δ is the distance between the locations of c_2 and c_1, in the present example it would be the capillary length. Alternately, c_2 and c_1 may also be the concentrations at the ore surface and in the bulk gas phase respectively. Then δ is the thickness of the diffusion gas boundary layer. Introducing Equation (51) into (49) yields

$$j = \frac{D}{\delta}\,(c_2 - c_1) \tag{52}$$

The ratio D/δ is sometimes termed mass transfer coefficient β. Equation (52) then changes into

$$j = \beta\,(c_2 - c_1) \tag{53}$$

Equation (53) has the advantage that it can formally express a flux caused by any concentration difference. It is often simple to find experimentally a relation between a flux and the appertaining driving concentration difference, and then to express the coefficient between both as a mass transfer coefficient. A comparison with Equation (1) shows that equations of the type of Equation (53) can also be applied to chemical reactions at the phase boundary. Instead of β, the rate constant k is then used, but the mathematical form of Equation (53) remains the same. It is the practical applicability, which makes Equation (53) so extremely suitable for the description of kinetic phenomena like those of iron ore reduction.

For the description of gas diffusion it is more practical to express the gas concentration in terms of the partial pressure p instead of the concentration c. Both values are interrelated by

$$c = \frac{p}{RT} \tag{54}$$

Although Equations (51) and (53) are valid for a constant concentration field, i.e., for a steady state, they are also applicable to situations where the concentration difference $c_2 - c_1$ changes during the process from an initially maximum value to zero, i.e., when equilibrium is attained. In contrast to a really time-dependent concentration field these changes are slow. The process is in a so-called quasi-steady state. This state can be treated in the same way as a steady state with a constant concentration field. The criterion for its validity is that capacity effects may be neglected.

The rate equations described contain quantities related to the particular geometry (mass exchange area A) and to material properties (the kinetic coefficients). In the following some definitions are given:

1) The *degree of reduction* $\Re$ is the ratio between the quantity of oxygen removed O_r and the quantity of oxygen initially present O_i:

$$\Re = \frac{O_r}{O_i} \tag{55}$$

Frequently the degree of reduction is expressed in percent (= 100 $\Re$).

2) *Reduction Rate.* When discussing the reduction kinetics, the rate of reduction, $\dot{\Re}$, is defined by

$$\dot{\Re} = \frac{\mathrm{d}\Re}{\mathrm{d}t} \tag{56}$$

3) *Effect of Diffusional Flows.* Because the reduction of ore by a gas does not result in a change in the number of moles in the gaseous phase (e.g., 1 mol CO gives 1 mol CO_2), the *total pressure* inside the pores of the ore does not change. The transport of matter occurs exclusively via the diffusion brought about by the difference in *partial pressure* of the gas components. The partial pressure of the

inert gas components present in the reducing gas is the same everywhere inside the ore particle. Hence, no macroscopic transport of these components takes place. Although during reduction with carbon monoxide inert gas is transported from the outside to the interior (corresponding to the direction of the CO flow toward the center) the carbon dioxide flow transports inert gas from the interior to the outside, the two effects cancelling each other. Only when hydrogen is used as a reducing agent is there a small net flow of inert gas from the interior to the exterior. This occurs because water vapor molecules have a significantly larger cross-sectional area than hydrogen molecules. Thus, the partial pressure of the inert gas is slightly lower in the interior of the ore than in the surroundings.

The flux of gaseous species diffusing inward, $j = 1/A \cdot \mathrm{d}n/\mathrm{d}t$, is related to the flux of the gaseous species diffusing outward via the stoichiometry of the reduction reaction:

$$j_1 = -j_2 \tag{57}$$

Expressing both fluxes by Equation (49) and denoting the respective diffusion coefficients of gas 1 in gas 2 and vice versa with D_{12} and D_{21}, yields:

$$D_{12}\,\frac{\mathrm{d}p_1}{\mathrm{d}x} = -D_{21}\,\frac{\mathrm{d}p_2}{\mathrm{d}x} \tag{58}$$

The sum of the partial pressures is constant ($p_1 + p_2 = p_{\mathrm{tot}}$), hence:

$$\frac{\mathrm{d}p_1}{\mathrm{d}x} = -\frac{\mathrm{d}p_2}{\mathrm{d}x} \tag{59}$$

Thus:

$$D_{12} = D_{21}$$

When considering the effect of the diffusion on the reduction it is, therefore, irrelevant whether the diffusional flow of the reducing gas into the ore or whether the outward flow of the oxidized gas from the interior to the surface of ore is considered. This is possible because the diffusion coefficients for the two counterflowing gas streams are equal.

Model Representations. The phenomena taking place in the *gaseous phase* and depicted in Figure 28 can be modeled as follows. In a first step, the reducing gas diffuses from the main flow through the gaseous diffusion boundary layer to the ore particle (step a in Figure 28). The transport within the ore particle is governed by diffusion inside the macropores (b) and the micropores (c). The distinction between macro- and micropores is determined by the mean free path of the gas molecules. Whenever the mean free path is large with respect to the pore diameter, the number of collisions between the gas molecules is small with respect to those between the gas molecules and the pore walls. In this case gas transport no longer obeys the laws of diffusion valid for free space, which is also valid for macropores with some geometric restrictions, but is determined by Knudsen diffusion, for which the diffusion coefficient follows a different law. Within the square denoted by (d), Within the square denoted by (d), the phase boundary reaction of oxygen separation from the solid ore crystal by the reducing gas takes place at the ore – gas interface. As a consequence of oxygen separation the ore becomes supersaturated with iron, leading to the precipitation of iron at a site where nucleation is favored. This site is different from that of oxygen removal, so that solid state diffusion of iron to the nucleation site is a further reaction step. The oxidized reducing gas (here water vapor) is transported to the exterior by the flow of gas in the opposite direction to the reducing gas and along the same path (steps f and g).

In principle, each of the various stages constituting the transport and conversion of matter, as depicted in Figure 28, can be rate determining. It may also be possible that several resistances are of about equal magnitude and thus together determine the reaction rate. Depending on the specific circumstances, an ore may be dense and yield a dense or a porous reaction product upon reduction; also, reduction may take place at high or low temperatures. Diffusion is only slightly affected by temperature, whereas the phase boundary reactions in general require high activation energies and are therefore strongly dependent on temperature. The result is that the rate-determining step of the overall reaction changes with varying temperature (cf. for example the Boudouard reaction rate constants in Fig. 10). A detailed discussion follows on the separate stages of the reduction process and for the case where they represent the largest resistance.

Gaseous Transport.

Diffusion through the Outer Gas Boundary Layer. The first transport resistance is that of transport of gas through the adjacent gaseous boundary layer (see Fig. 28). The flow of matter through this layer is determined by Fick's first law with the partial pressure difference as the driving force (Eqs. 49 and 54). If the partial pressure gradient $-\mathrm{d}p/\mathrm{d}x$ is replaced by $\Delta p/\delta_\mathrm{N}$ (Δp = pressure difference, δ_N = thickness of the Nernst's diffusion boundary layer) and the ratio D/δ_N replaced by the mass transfer coefficient β, Equation (49) takes the form

$$j = \frac{\beta\,\Delta\mathrm{p}}{RT} \tag{60}$$

The mass transfer coefficient β is inversely proportional to the thickness δ_N of the boundary layer. The latter decreases with increasing gas flow rate.

Reduction experiments in the laboratory have shown that the reduction rate of a Fe_2O_3 layer in carbon monoxide at 1000 °C is a function of the gas flow rate (see Fig. 29). The rate of reduction is expressed in terms of the degree of reduction attained after a certain time from the beginning.

Figure 29. Relation between gas flow rate and reduction rate of iron(III)oxide in carbon monoxide at 1000 °C [43]

In the reduction of an array of particles (e.g., a burden) the boundary layer around each particle is determined by the individual fluid dynamic conditions. The mass transfer coefficient β in the burden can be calculated from the experimentally determined heat transfer coefficient which is easier to evaluate. Such calculation is possible on the basis of the physical similarity of heat transfer and mass transfer. For the conditions prevailing in the blast furnace the expression for β takes the form

$$\beta = \mathrm{C}\,\frac{u^{0.7}}{d^{0.3}} \tag{61}$$

where C is a constant, u the superficial gas velocity, and d the particle diameter.

For constant superficial velocity the mass transfer coefficient decreases slightly with increasing particle diameter.

The inverse of the mass transfer coefficient may be termed specific resistance. Comparison of this resistance, as defined by Equation (61), with the resistances of the other partial reaction steps of iron ore reduction kinetics (which are described below), shows that under the fluid dynamic conditions of packed beds in the blast furnace, gas transport through the outer boundary layer requires a partial pressure difference Δp_g as the driving force, which is only about 2 % of the required total partial pressure difference Δp_tot for all the reaction steps in total. That means, the transport resistance of the outer gas boundary layer may almost be neglected.

Diffusion in Macro- and Micropores. The second transport mechanism shown in Figure 28 is the gaseous diffusion in the macro- and micropores. The diffusion law (Eq. 35) governs the diffusion in *macropores.* However, the diffusion coefficient D has to be corrected in two

ways. The gas diffusion in a porous solid takes place only in the volume occupied by the pores which is a fraction γ of the total volume. Therefore, D for the bulk gas phase is multiplied by the porosity γ to give the pore diffusion coefficient D_{P}. In addition, the course of the pores in relation to the direction of the flow has to be taken into account. This is achieved by the introduction of the *tortuosity factor* ξ which gives D_{P} the expression:

$$D_{\mathrm{P}} = D\gamma\xi \tag{62}$$

For short time spans, i.e., from a few seconds to several minutes, depending on temperature and stage of reduction, the diffusion may be assumed to take place in the steady state and the flux j assumed to be constant. In that case Equation (53) takes the form

$$j = \frac{D_{\mathrm{P}}}{RT} \cdot \frac{(p_{\mathrm{a}} - p_{\mathrm{P}})}{x} \tag{63}$$

Here, p_{a} is the partial pressure of the reducing gas component at the interface between the ore and the boundary layer and p_{P} the partial pressure at the interface in the solid where transport by diffusion ceases and the chemical reaction occurs; x is the linear distance between the locations of p_{a} and p_{P}.

If the resistances representing the outer boundary layer and the phase boundary reaction at the ore interface are negligible, the partial pressure p_{a} may be replaced by p_0, the partial pressure of the reducing gas component in the bulk phase, while p_{P} may be replaced by p^*, the equilibrium partial pressure

$$j = \frac{D_{\mathrm{P}}}{RT} \cdot \frac{(p_0 - p^*)}{x} \tag{64}$$

where p^* is dependent on the temperature and on the reduction step considered (Fe_2O_3 to Fe_3O_4, Fe_3O_4 to FeO, or FeO to Fe). The corresponding values may be obtained from the Richardson diagram (see Fig. 12). Regarding technical problems the dependence of the flux j on temperature and total pressure is important. In Equation (65) $(p_0 - p^*)$ increases with increasing pressure and p^* depends on the temperature as may be seen from Figure 12. The pore diffusion coefficient changes with pressure and temperature – as may be determined experimentally or from the kinetic gas theory – according to:

$$D_{\mathrm{P}} \sim \frac{1}{P} \tag{65}$$

$$D_{\mathrm{P}} \sim T^n, 1.75 < n < 2 \tag{66}$$

As the pressure dependence of $(p_0 - p^*)$ is the inverse of that of D_{P} the diffusional flux j is independent of pressure.

The flow of matter in *micropores* is governed by the same expression valid for the flow in macropores (Eq. 63). However, in this case D_{P} must be replaced by the Knudsen diffusion coefficient D_{K}. For the component a this coefficient D_{K} may be calculated from the expression [50]

$$D_{\mathrm{K,a}} = \frac{d}{6}\left(\frac{8\,RT}{\pi M_{\mathrm{a}}}\right)^{1/2} \tag{67}$$

Here, d is the pore radius which is less than the mean free path λ of the gas molecules. As D_{K} is independent of pressure but $(p_0 - p^*)$ depends on pressure, the flow of matter caused by Knudsen diffusion increases with increasing total pressure, provided $d < \lambda$ despite the increase in pressure. The temperature dependence of the diffusion in micropores is lower than that of macropore diffusion.

Interfacial Reaction. The interfacial reaction phenomenon shown in Figure 28 has been studied in several respects. The results have been published in many individual publications; an extensive review of these complex phenomena is also available [43]. A simplified version is discussed here. The oxides of iron, hematite ($FeO_{1.5}$), magnetite ($FeO_{1.33}$), and wustite ($FeO_{\approx 1.08}$) have a close-packed structure of oxygen ions (see page 46). The tetrahedral and octahedral interstices of this structure are occupied with Fe^{2+} and Fe^{3+} ions. The transformation of hematite to magnetite requires a redistribution of the oxygen ions from the hexagonal to the face-centered cubic structure. During transformation of magnetite to wustite the oxygen ions are not rearranged, only the iron : oxygen ratio changes.

Reduction of Hematite to Magnetite. During reduction of hematite oxygen is removed at the gas – hematite interface from the hematite lattice according to

$$\mathrm{O^{2-} \rightarrow O + 2\,e^-}$$

The iron ions react with the free electrons according to:

$$\mathrm{2\,Fe^{3+} + 2\,e^- \rightarrow 2\,Fe^{2+}}$$

Whenever at the surface of the oxide the ratio $Fe^{3+}:Fe^{2+} = 2$ is reached, the hexagonal oxygen lattice transforms into the cubic magnetite lattice and hematite becomes covered with a thin layer of magnetite. The gas does not have direct access anymore to the hematite phase so that further oxygen removal occurs from the magnetite lattice (see Fig. 30).

Figure 30. Reduction of hematite to magnetite

If the composition of the reducing gas is in equilibrium with magnetite (see Fig. 15), the removal of oxygen can proceed only to a level corresponding to an iron activity that is determined by the oxygen partial pressure at the gas – magnetite interface, according to Figure 17. This iron activity is higher than that at the hematite – magnetite interface (see Fig. 17). This difference in iron activity, which is opposite to that in oxygen activity, leads to diffusional flows of iron and oxygen ions. Experiments show that the differences in activity in magnetite and wustite result in relatively high diffusional flows of iron ions and electrons and in a small flow of oxygen ions. On the other hand, in hematite the transport of matter is primarily the result of the diffusion of oxygen ions. Accordingly, the reduction process depicted in Figure 30 proceeds in such a manner that the removal of oxygen at the magnetite – gas interface leads to an iron activity a'_{Fe}. Iron ions and electrons diffuse through the magnetite layer and react at the hematite – magnetite interface – where the iron activity equals a''_{Fe} – according to:

$$4\,Fe_2O_3 + Fe^{2+} + 2\,e^- \rightarrow 3\,Fe_3O_4 \qquad (68)$$

As a result the interface moves further into the hematite phase.

If reduction proceeds perpendicular to the *c*-axis of the hematite, the reduction rate is determined by the diffusion rate of the iron ions through the magnetite layer previously formed. For high rates of reaction (68) the activities a''_{Fe} and a'_{Fe} at the interfaces are fixed. Hence, the driving force $(a'_{Fe} - a''_{Fe})$ remains constant. However, the diffusion length s through the growing magnetite layer which is the thickness of the layer, increases during the reaction, and hence, the concentration gradient $(a'_{Fe} - a''_{Fe})/s$ decreases. The flux is expressed by Equation (52). Considering that here the flux j is proportional to the layer growth rate ds/dt and that δ is equal to the layer thickness s, gives $ds/dt \sim (c'_{Fe} - c''_{Fe})/s$. The growth rate ds/dt is indirectly proportional to the thickness itself. Integration of this equation leads to a parabolic rate law for the layer growth

$$s = k \cdot t^{1/2} \qquad (69)$$

where k is a constant and t is the time. If the reduction of hematite occurs parallel to the *c*-axis, a parabolic rate law is not observed experimentally. It is assumed that in that case the interfacial reaction (68) becomes rate determining.

Figure 31. Geometric and stoichiometric relationships during the hematite reduction

The geometric and stoichiometric conditions during the reaction of 1 mol magnetite at the magnetite – gas interface are shown in Figure 31. The 3 mol iron ions produced, together with the electrons, react with 12 mol hematite to produce 9 mol magnetite at the hematite – magnetite interface. As 12 mol hematite contain 24 mol iron, but 9 mol magnetite contain 27 mol iron, 1 mol magnetite vanishes at the magnetite – gas interface at the same time. Because the spatial requirement of magnetite exceeds that of the previously present hematite, technical reduction processes frequently give rise to unde-

sirable structural disorders. On the other hand, these lead to an increase in the interfacial area exposed to the gas and, hence, an increase in the reduction rate.

Reduction of Magnetite to Wustite. This reaction proceeds similar to that of hematite to magnetite. The removal of oxygen from the wustite surface liberates iron ions that subsequently diffuse through the wustite layer, that grows at the expense of magnetite, and react with magnetite to form wustite. The removal of oxygen from the wustite phase, in which the oxygen content varies between 24.5 % and ca. 22 %, takes place in a similar fashion. The iron activity at the surface increases as dictated by the removal of oxygen. By diffusion of iron ions an activity is eventually established in the interior of the wustite phase that corresponds to the oxygen partial pressure (see Fig. 17).

Reduction of Wustite to Metallic Iron. This may give rise to two limiting cases concerning the morphology of the phases, as illustrated in Figure 32.

The spherical precipitations inside the wustite crystal and the lens-shaped precipitation of iron on a wustite surface are depicted in Figure 32 A and B; upon further reduction this usually leads to the formation of porous sponge iron. In this case oxygen is removed *directly* from wustite by direct contact between the gas and the wustite phase. Pores are formed at the sites from which the oxygen was removed; the pore walls are subsequently covered with metallic iron. The iron ions and electrons that are liberated as a result of the oxygen removal diffuse from the removal site to the metallic iron and condense there to form metallic iron. Iron ions and electrons do not recombine at the removal site of oxygen to produce metallic iron because nucleation is impeded there.

The reduction mechanism in the presence of a protective iron layer on the wustite surface is illustrated in Figure 32 C. In this case oxygen must diffuse through the iron layer to react with the reducing gas. The permeability $c_O D_O$ of the iron for oxygen is small because of the low solubility c_O of oxygen in iron. Thus, this morphology of the formation of iron leads to a slow reduction rate compared to the mechanism illustrated in Figure 32 A and B.

The conditions that play a role in the mechanism of iron formation are still unclear in many respects. However, it was established experimentally that the reduction of wustite with a high concentration of vacant iron sites, i.e., with a high oxygen content according to Figure 14, generally produces a porous iron layer. At lower concentrations of vacant iron sites the formation of a protective iron layer was observed. Generally, protective iron layers are formed around the wustite grains whenever magnetite ore is reduced but porous iron is formed whenever

Figure 32. Morphology and location of the phases during the reduction of wustite to iron
A) Precipitation of iron on the surface; B) Iron precipitation within the oxide body; C) Reduction in the presence of a protective iron layer

hematite ore is reduced. In the latter case the reduction rate is higher because reducing gas has direct access to the oxygen lattice. Hence, magnetite ore is usually oxidized to hematite during sintering or pelletizing.

Under special conditions iron whiskers may be formed on the wustite surface. This may result in a significant change in volume of the ore particles, particularly when the grain structure of the particles was already weakened during the hematite – magnetite reduction stage. This form of iron precipitation is, therefore, undesirable in technical reduction processes.

Rate Laws. When discussing the rate laws that govern phenomena belonging to the group of "reduction reaction," important in technical processes, a few simplified assumptions can be made on the basis of the technical boundary conditions.

1) As during the reduction step hematite ($FeO_{1.5}$) $\rightarrow$ wustite ($FeO_{1.05}$) only ca. 1/3 but during the step wustite ($FeO_{1.05}$) $\rightarrow$ iron (Fe) ca. 2/3 of the total removable oxygen is eliminated, and as moreover the rate of the second of these two steps of the overall reaction is slower than that of the first, the latter step is solely taken into account. The error of that simplification is small.
2) For the ores processed in industrial reduction processes it can be assumed that porous iron, as illustrated in Figure 32 A, is formed. This means that the reducing gas has access to a portion of the oxide surface during the entire reduction process.
   The rate of oxygen removal from the interface is, analogue to Equation (2), given by

$$\frac{\mathrm{d}n_\mathrm{O}}{\mathrm{d}t} = \frac{k'}{RT} A\,(p_\mathrm{P} - p*) \tag{70}$$

   where p_P is the partial pressure of the reducing gas at the interface and k' is the rate constant in m/s. However, the oxygen removal as given by this expression is only formally correct. In the case of Figure 32 A for example, the reaction surface area A is only part of the total surface area that is exposed to the gas [49]. Moreover, in the reduction of porous oxides the effective surface depends on the porosity. It was found that the activation energy of oxygen removal prior to the formation of metallic iron is 170 kJ/mol and decreases to ca. 60 kJ/mol after the formation of metallic iron. This means that for the technically important case of reduction accompanied by the formation of iron the temperature dependence on the rate of the interfacial reaction is relatively small. The pressure dependence of the flux of material $\mathrm{d}n_\mathrm{O}/\mathrm{d}t$ follows from the pressure dependence of the term $(p_\mathrm{P} - p^*) = \Delta p$. The linear pressure dependence $\Delta p_2 = \Delta p_1 \cdot P_2/P_1$ is masked by side effects at higher pressures.

2.3.1.2. Rate Laws of Complex Reduction Reactions

Dense Ore Particles, Porous Iron Layers.

Gas Diffusion is Rate Determining. When discussing the technically important rate laws describing reduction processes, it is assumed that the ore particles may be approximated by a sphere.

During reduction of dense ores a layer of porous iron normally surrounds a core of unreduced ore. Whenever the diffusion of the reducing gas component i through the reduced layer is rate determining, Equation (49) with $j = 4\,\pi\,r^2 \cdot \mathrm{d}n_i/\mathrm{d}t$ and substituting p/RT for c and $\mathrm{d}r$ for $\mathrm{d}x$ takes the following form:

$$\frac{\mathrm{d}n_i}{\mathrm{d}t} = -\frac{4\pi r^2 D_{\mathrm{P},i}}{RT}\,\frac{\mathrm{d}p_i}{\mathrm{d}r} \tag{71}$$

where $r_0 > r > 0$ is the radius of the sphere. If p_0 and p_P are the partial pressures of the reducing gas in the bulk gas phase and at the gas – wustite interface near the unreduced core, respectively, and r' is the radius of the unreduced core, then integration of Equation (71) over the radius r between the limits r_0 and r' as well as over the partial pressure between the limits p_0 and p_P gives

$$\frac{\mathrm{d}n_i}{\mathrm{d}t}\left(\frac{1}{r_0} - \frac{1}{r'}\right) = \frac{4\pi D_{\mathrm{P},i}}{RT}\,(p_0 - p_\mathrm{P}) \tag{72}$$

Because of the stoichiometric relationship (CO, H_2) + O = (CO_2, H_2O) the number of moles of reducing gas $\mathrm{d}n_i$ diffusing into the ore particle equals the number of moles $\mathrm{d}n_\mathrm{O}$ of oxygen removed and diffusing out

$$\frac{\mathrm{d}n_i}{\mathrm{d}t} = -\frac{\mathrm{d}n_\mathrm{O}}{\mathrm{d}t}$$

The number of moles of oxygen diffusing out in time $\mathrm{d}t$ brings about a displacement of the reacting interface over a distance $\mathrm{d}r'$ given by

$$\frac{\mathrm{d}n_\mathrm{O}}{\mathrm{d}t} = 4\,\pi\,(r')^2 d_\mathrm{O}\,\frac{\mathrm{d}r'}{\mathrm{d}t} \tag{73}$$

where d_O is the oxygen content per unit volume of the ore (mol/cm^3).

Instead of the magnitude of the flux of oxygen, the reduction rate is usually employed. According to Equation (55) the following relation exists between the degree of reduction $\Re$, the initial volume V_0 and the volume V' of the unreduced spherical core of the ore particle:

$$\Re = 1-\frac{V'}{V_0} = 1-\frac{(r')^3}{(r_0)^3} \tag{74}$$

Substitution of Equations (73) and (74) into Equation (72), gives the following expression for the reduction rate $\dot{\Re}$

$$\dot{\Re} = \frac{\mathrm{d}\Re}{\mathrm{d}t} = \frac{3\,D_{\mathrm{P},i}\,(p_0-p_\mathrm{P})}{r_\mathrm{O}^2 d_\mathrm{O}\left[(1-\Re)^{-1/3}-1\right]RT} \tag{75}$$

In the case assumed here that solely pore diffusion is rate determining, the equilibrium partial pressure is established at the surface of the unreduced core, i.e. $p_\mathrm{P} \cong p^*$. Then, the reduction rate increases with increasing diffusion coefficient and concentration difference of the reducing gas and decreases with the square of the radius of the sphere (see Eq. 75). The effect of the degree of reduction on the reduction rate is particularly noticeable for low and high values of $\Re$.

Phase Boundary Reaction is Rate Determining. The following expression is valid when the phase boundary reaction is slow and, hence, rate determining

$$\dot{n}_\mathrm{O} = \frac{k'}{RT} A\,(p_\mathrm{P}-p*) \tag{70}$$

Here, $\dot{n}_\mathrm{O} = \mathrm{d}n_\mathrm{O}/\mathrm{d}t$, $A = 4\pi r'^2$. As $\dot{\Re} = \dot{\mathrm{n}}_\mathrm{O}/\mathrm{n}_\mathrm{O}^0$, where n_O^0 is the initial number of moles of oxygen present in the ore particle, and as

$$n_\mathrm{O}^0 = d_\mathrm{O}\cdot V_0 = d_\mathrm{O}\,\frac{4}{3}\pi r_0^3$$

Equation (70) yields with Equation (74)

$$\dot{\Re} = \frac{3k'(1-\Re)^{2/3}\,(p_\mathrm{P}-p*)}{RT\cdot d_\mathrm{O} r_0} \tag{76}$$

In the case assumed here that solely the phase boundary reaction is rate determining, the outer pressure p_0 is established in front of the reaction surface, i.e. $p_\mathrm{P} \cong p_0$.

Gas Diffusion and Phase Boundary Reaction have Similar Rates. In cases where the resistances representing the interfacial reaction and the pore diffusion are about equal in magnitude, the partial pressure of the reducing gas at the interface p_P is between p_0 and $p_0 > p_\mathrm{P} > p^*$.

Elimination of p_P from Equations (75) and (76) gives an expression for the reduction rate $\dot{\Re}$ in terms of the resistances representing diffusion and phase boundary reaction

$$\dot{\Re} = \frac{3\,D_\mathrm{P}\,k'(1-\Re)^{2/3}(p_0-p*)}{\left\{d_\mathrm{O} r_0 D_\mathrm{P} + r_0^2 d_\mathrm{O} k'\left[(1-\Re)^{1/3}-(1-\Re)^{2/3}\right]\right\}RT} \tag{77}$$

Integration yields a direct relation between the degree of reduction $\Re$ and the reaction time t

$$\frac{k'}{r_0 d_\mathrm{O} RT}\,(p_0-p*)\,t = \left[1-(1-\Re)^{1/3}\right] + \frac{k' r_0}{D_\mathrm{P}}\left[\frac{1}{2}-\frac{\Re}{3}-\frac{(1-\Re)^{2/3}}{2}\right] \tag{78}$$

Whenever the *phase boundary reaction* is rate determining, $D_\mathrm{P} >> RT\,k\,r_0$. In this case and under a given set of conditions $k'\,(p_0 - p^*) = k_\mathrm{c}$ and Equation (78) takes the form as suggested by McKewan [51]

$$d_\mathrm{O} r_0\left[1-(1-\Re)^{1/3}\right] = k_\mathrm{c}\,t \tag{79}$$

Whenever *gaseous diffusion* is rate determining, $D_\mathrm{P} << k'\cdot r_0$. In this case the first term on the right in Equation (78) may be neglected and Equation (78) takes the form

$$d_\mathrm{O} r_0^2\left[\frac{1}{2}-\frac{\Re}{3}-\frac{(1-\Re)^{2/3}}{2}\right] = \frac{D_\mathrm{P}\,(p_0-p*)}{RT}\,t \tag{80}$$

In the early stages of reduction the porous iron layer is thin and, hence, the path for the diffusing gas is short. Thus, initially the reduction rate is determined by the phase boundary reaction. In the later stages the gas diffusion becomes rate determining because of the increase in length of the diffusion path; this was experimentally verified.

For the experimental verification, reference is made to Equations (79) and (80). For a given degree of reduction $\Re$, a given ore and a fixed composition of the reducing gas the following expressions may be derived from Equations (79) and (80)

$$\log t = \log K_1 + \log r_0 \tag{81}$$

$$\log t = \log K_2 + 2 \log r_0 \quad (82)$$

The experimentally observed relation between log t and log r_0 is shown in Figure 33 for the reduction of hematite pellets in hydrogen at 750 °C and pellet radii between 8.5 and 17.5 mm. According to Equations (81) and (82) the slope of the lines should indicate whether the reduction time is primarily determined by the interfacial reaction or by gaseous diffusion. For low degrees of reduction the slope is closer to one whereas for higher degrees of reduction it is closer to two. From these observations it is evident that in the beginning the reduction rate is primarily determined by the interfacial reaction whereas in the later stages pore diffusion becomes rate determining.

Figure 33. Reduction time t (min) needed to attain a given degree of reduction as a function of the pellet radius r_0 (mm) [19]

Porous Ore Particles, Porous Iron Layers. As mentioned in the beginning of this section, the mathematical expressions so far discussed are valid for the reduction of dense particles on which porous iron layers are formed during the reduction. The mathematical treatment of the reduction, particularly of porous iron oxide particles, is due to L. von Bogdandy and H. G. Riecke [52] as based on concepts proposed by E. W. Thiele. The basic premise is that the reducing gas diffuses into the spherical ore body and that the reaction occurs on the entire internal surface area of the sphere. Here the phase boundary reaction rate is defined by a volumetric reaction rate constant $k_V = k' A/V$ (s^{-1}), where A/V is the internal surface area per volume of the ore particle. The spherical ore body is divided into infinitely small shells of volume $4\pi r^2 dr$, where r is the radial coordinate. The reaction rate dv is the number of moles of oxygen removed from the ore per unit of time in this shell. As the removal of oxygen generates a corresponding decrease of the reducing gas concentration in the volume element, the concentration of this gas is higher at the position $r + dr$ than at the position r. The concentration difference generates an inward-directed diffusion flow of the reducing gas, for instance CO, and an outward flow of the reaction product, for instance CO_2. The difference of the diffusion flow $d\dot{n}_{r+dr}$ at the position $r + dr$ and $d\dot{n}_r$ at the position r must be equal to the consumption of gas by the phase boundary reaction dv. The phase boundary reaction is expressed as

$$dv = 4\pi r^2 dr \frac{k_V}{RT}(p_r - p*) = 4\pi r^2 dr \frac{k_V}{RT}\Delta p_r \quad (83)$$

where p_r is the partial pressure of the reducing gas in the volume element at radius r. The pressure difference $p_r - p*$ can be expressed as Δp_r . The difference of the diffusional flow between $r + dr$ and r is obtained by derivation of the diffusion equation with respect to r. For the diffusing gas CO, for example, the diffusional flow is expressed as

$$\dot{n}_{CO} = 4\pi r^2 \frac{D_P}{RT}\frac{(p_{r+dr} - p_r)}{dr} = 4\pi r^2 \frac{D_P}{RT}\frac{d(\Delta p_r)}{dr} \quad (84)$$

Derivation with respect to r yields

$$d\dot{n}_{CO} = 8\pi r dr \frac{D_P}{RT}\frac{d(\Delta p_r)}{dr} + 4\pi r^2 \frac{D_P}{RT}\frac{d^2(\Delta p_r)}{dr^2} dr \quad (85)$$

As $d\dot{n}_{CO}$ in moles per time is equal to dv in moles per time, Equations (83) and (85) must be equal. That yields

$$\frac{k_V}{D_P}(\Delta p_r) = \frac{2}{r}\cdot\frac{d(\Delta p_r)}{dr} + \frac{d^2(\Delta p_r)}{dr^2} \quad (86)$$

This equation contains the second derivative of the partial pressure difference because not only the partial pressure gradient for diffusional flow as in the previously described case of an inert porous iron layer, but also an additional change of partial pressure due to the chemical reaction in the pore must be considered.

The boundary conditions for the solution of Equation (86) are found as follows. The pressure difference Δp_r at the outer surface r_0 is Δp_0. In the core at $r = 0$, Δp_r has a minimum. Thus $\Delta p_r/dr$ is zero at this point. With these two boundary conditions, Equation (86) can be solved to give

$$\frac{\Delta p_r}{\Delta p_0} = \frac{p_r - p^*}{p_0 - p^*} = \frac{r_0}{r}\cdot\frac{\sinh\left[\sqrt{k_V D_P}\cdot r\right]}{\sinh\left[\sqrt{k_V/D_P}\cdot r_0\right]} \quad (87)$$

The equation describes the dimensionless pressure difference $(p_r - p^*)/(p_0 - p^*)$ as a function of the dimensionless radius r/r_0 of the ore sphere. The ore radius r_0 and the ratio between the reaction rate constant and the pore diffusion coefficient k_V/D_P are the parameters. The functional relationship between $(p_r - p^*)/(p_0 - p^*)$ and r for various values of the parameters is shown in Figure 34. The results are discussed later.

Before discussing Figure 34, a more general consideration is useful. To this end the dimensionless parameter $k_V\, r_0^2/D_P$, which combines the influences of r_0 and k_V/D_P is introduced. According to the value of this parameter Equation (87) has two limiting cases, namely $k_V\, r_0^2/D_P >> 1$ or $k_V\, r_0^2/D_P << 1$. In the first case, the phase boundary reaction is fast and/or the particle radius is large. As a consequence of the fast reaction, reduction starts at the surface. The CO partial pressure p_0 falls steeply to the equilibrium value p^* within a small layer of thickness Δr. The particle behaves like a dense ore. During the reduction process the layer and with it the steep partial pressure gradient of the reducing gas shifts gradually from the outer surface into the ore body. This is schematically shown in Figure 35. In the second case, pore diffusion is fast in comparison to the phase boundary reaction, and/or the particle radius is small. In this case the gas is distributed infinitely fast and uniformly over the entire particle. At any point of the particle, the partial pressure is p_0, and hence, the driving force has its maximum Δp_0. This latter case represents the maximum possible reduction rate v_{max}. It follows from Equation (83) that

$$v_{max} = \frac{4}{3}\pi r_0^3 \frac{k_V}{RT}\Delta p_0 \quad (88)$$

For the general case the actual reaction rate v is obtained by inserting Δp_r from Equation (87) into (83) and then integrating Equation (83) between $r = r_0$ and $r = 0$. This yields, if the reduction rate is dimensionlessly expressed by

$$\dot{\Re} = \frac{v}{\frac{4}{3}\pi r_0^3 \cdot d_O} \quad (89)$$

and if $\varphi = r_0(k_V/D_P)^{\frac{1}{2}}$ is inserted in Equation (87):

$$\dot{\Re} = \frac{v}{\frac{4}{3}\pi r_0^3 \cdot d_O} = \frac{3\, D_P}{r_0^2 \cdot d_O\, RT}\Delta p_0 \left[\coth\varphi - \frac{1}{\varphi}\right] \quad (90)$$

The reduction rate can be expressed in terms of the maximum reduction rate as $v/v_{max} = \eta$. In this way, η expresses the effectivity of the reduction. Then, it follows from Equations (88) and (90)

$$\eta = \frac{3}{\varphi}\left(\frac{1}{\varphi} - \coth\varphi\right) \quad (91)$$

From Equation (91) it follows that

$$\lim_{\varphi\to 0}\eta = 1$$

and hence

$$\dot{\Re} = \frac{k_V}{d_O\, RT}\Delta p_0 \quad (92)$$

and that

$$\lim_{\varphi\to\infty}\eta = \frac{3}{\varphi}$$

and hence

$$\dot{\Re} = \frac{3\cdot(k_V D_P)^{1/2}}{r_0 d_O\, RT}\Delta p_0 \quad (92a)$$

Thus, at the maximum reduction rate ($\varphi \to 0$) the rate is independent of the particle radius and depends on the phase boundary reaction rate only. As mentioned before, reduction takes place uniformly over the entire ore body as at each point of the ore the maximum partial pressure difference Δp_0 is present. At $\varphi \to \infty$ the rate is inversely proportional to the particle radius and

Figure 34. Partial pressure of the reducing gas in the interior of the porous ore sphere during the formation of porous iron

dependent on the square root of the product of the phase boundary reaction rate constant and the pore diffusion coefficient. Reduction takes place in a small reaction layer moving into the ore body. Reduction is determined by diffusion in the pores and by the phase boundary reaction rate constant k_V in the reaction layer.

Figure 35. Partial pressure profile inside a porous ore sphere during formation of a reduction zone Δr

Between the limiting cases $\varphi = 0$ and $\varphi = \infty$ the dimensionless concentration gradient $(p_r - p^*)/(p_0 - p^*)$ in the ore is the more steep the larger the parameter k_V/D_P and the larger the particle radius r_0. This is shown in Figure 35.

Synopsis. A summary of the effects of various phenomena concerning the reduction rate, as obtained from the partially overlapping models of McKewan and von Bogdandy et al., is presented in Table 11. The material constants to be used in approximate calculations are:

k' = interfacial reaction rate constant,
A = activation energy of the interfacial reaction,
D_i = diffusion coefficient of the reducing gas component i,
γ = ore porosity,
ξ = tortuosity factor,
a_i = internal surface area of the ore.

The values of k' and A as determined by various investigators may be obtained from Figure 36 (lines 1 – 21).

Particular attention should be paid to the following.

- The *reaction rate constant* for the reduction of the homogeneous wustite phase, i.e., without metallic iron formation, is significantly lower than that observed when metallic iron has been produced.
- The *activation energy* for the reduction in the presence of iron is significantly lower than that observed prior to the formation of metallic iron.

Table 11. Dependence of the reduction rate on various experimental parameters (k' = rate constant of interfacial reaction; [52, 53]. A = activation energy of interfacial reaction; D_i = diffusion coefficients of reducing gases; γ = ore porosity, ξ = tortuosity factor)

Conditions	Functional Relationship between $\Re$ and				Remarks	Model of
	Radius of ore sphere, r_0	Difference in partial pressure of reducing gas, $p_0 - p^*$	Total pressure, p_{tot}	Temperature, T		
$r_0 k' < D_P$	$\sim r_0^{-1}$	$\sim (p_0 - p^*)^a$	$\sim p^0$	$\sim \exp - A/RT$	low temperature[c] higher temperature, r_0 small, or r_0 large but only at initial reduction stage [d]	McKewan [52]
$r_0 k' > D_P$	$\sim r_0^{-2}$	$\sim (p_0 - p^*)^a$	$\sim p^{0a}$ $\sim p^{0b}$	$\sim T^{-1.7}$	higher temperature, r_0 large [d]	
$r_0^2 k_V < D_P$	$\sim r_0^0$	$\sim (p_0 - p^*)^a$	$\sim p^0$	$\sim \exp - A/RT$	lower temperature, r_0 small [d]	von Bogdandy, Riecke [53], reaction and diffusion in porous oxide
$r_0^2 k_V > D_P$	$\sim r_0^{-1}$	$\sim (p_0 - p^*)^a$	$\sim p^{0\ a}$ $\sim p^{0b}$	$\sim \exp - A/2RT$	higher temperature, r_0 large [d]	

[a] For the case of gas diffusion primarily in macropores, mean free path $\lambda < d$ (pore diameter), i.e., high pressure.
[b] $\lambda > d$, i.e., low total pressure.
[c] No good agreement with experiment.
[d] Good agreement with experiment.

Figure 36. A) Temperature dependence of the rate constant k' (cm/s) for the reduction of wustite; B) activation energy of the reduction reaction [49]

– The *reaction rate constants* for the *reduction* with *hydrogen* are higher than those for carbon monoxide.

The presence of metallic iron is responsible for an increase in the reduction rate, as a result of the catalytic effect of iron, causing a decrease in the temperature dependence of the rate. The values shown in Figure 36 are valid for the reduction of pure wustite. The reaction rates for wustite doped with other ions may be significantly different.

The *diffusion coefficients* D_i may be calculated from the expression [50]:

$$D_{12} = D_{21} \simeq 1.84 \cdot 10^{-1} \frac{T^{3/2}}{P\sigma_{12}^2} \left(\frac{M_1 + M_2}{M_1 M_2} \right)^{1/2} \quad (93)$$

where

$$\sigma_{12} = (\sigma_1 + \sigma_2)/2$$

is the average collision diameter of the gas molecules in mm; P the total gas pressure in bar; M_1, M_2 the molecular mass of the gas components. For details of calculation reference is made to [50].

The various ores and agglomerates differ considerably with respect to porosity, tortuosity factor and internal surface area, even prior to the reduction. Calculations are complicated by the fact that these quantities change during reduction in an unpredictable manner. Therefore, the values shown in Table 12 serve as guidelines only. The change in porosity and internal surface area during the reduction of pellets has been measured (see Fig. 37).

Table 12. Values of porosity γ and inner surface area a_i for various ores

Ore	γ, %	a_i, cm^2/cm^3
Kiruna, magnetite	1.3	0.38×10^3
Steep Rock	15.3	1.8×10^3
Mesabi Range, hematite	25 – 40	
Sinter (micropores <14 µm)	1 – 18	
Pellets	20 – 35	2×10^3

Hematite pellets (curve marked "unreduced" in Fig. 37) were prereduced to wustite at 750 °C. Using this wustite as a starting material, the reduction was interrupted at several predetermined degrees of reduction and porosity and internal surface areas were measured with a mercury porosimeter. The porosity increases from 25 % (hematite) to 35 % (wustite) and then to 50 % at a reduction degree of ca. 50 % (50 % iron, 50 % wustite), primarily because of an increase in the number of pores with radii $r < 5.10^{-5}$ cm that were hardly present in the starting material. As a result the internal surface area increases by about a factor of ten.

The mean free path λ of the reducing gas molecules is of the same order of magnitude as the radii of those pores that provide the major contribution to the internal surface area of the pellets (see Table 13). At normal pressure diffusion in these pores takes place via Knudsen diffusion.

Figure 37. Internal surface area and porosity of pellets as a function of the pore radius [45]

The evaluation of the *tortuosity factor* ξ can only be made indirectly via the determination of the pore diffusion coefficient D_{P}. However, ξ is usually used to calculate D_{P} from the diffusion coefficient D in the bulk gas phase. Therefore, the value of ξ is only of interest in modeling pore diffusion. The calculated values of ξ vary between 0.06 and 0.4 [19]. As a first approximation the following expression is valid where D_i has been calculated from Equation (93).

$$D_{\mathrm{P}} \simeq 0.2 D_i \quad (94)$$

Additional Formulations. R. Jeschar [54] proposed a dimensionless formulation of Equation (78) which is expressed here as follows:

$$\frac{(p_0 - p*)}{RT \cdot d_{\mathrm{O}}} Fo = \frac{1}{Da} \left[1 - (1 - \Re)^{1/3} \right] - \frac{1}{2} \left[1 - (1 - \Re)^{2/3} \right] - \frac{1}{3} \left(1 - \frac{1}{Sh} \right) \Re \quad (95)$$

Table 13. Mean free path $\overline{\lambda}\times 10^5$ (cm) in binary gas mixtures at a total pressure of 0.1 MPa

Temperature, K	Mean free path $\overline{\lambda}$ in mixtures of			
	$CO-N_2$	H_2-N_2	H_2-H_2O	$CO-CO_2$
773	2.64	3.34	3.57	2.63
973	3.58	4.44	4.76	3.71
1173	4.52	5.62	6.01	4.91
1373	5.53	6.84	7.32	6.22

with

$$Fo = \frac{D_P \cdot t}{r_0^2} \text{ (Fourier number)}$$

$$Da = \frac{k\prime \cdot r_0}{D_P} \text{ (Damköhler number)}$$

$$Sh = \frac{\beta \cdot r_0}{D_P} \text{ (Sherwood number)}$$

The term 1/3 $\Re/Sh$ expresses the diffusion in the outer gas boundary layer, which was already proven to have a negligible influence. It is not part of Equation (78). Except that term, (78) and (95) are in agreement. The advantage of using dimensionless quantities is that the number of process-relevant variables is reduced. In the present case, the five variables D_P, t, r_0, k', and β are reduced to the three really independent dimensionless variables Da, Fo, and Sh.

In the model for reduction of porous ores, Equation (92a) describes the limiting case that the phase boundary reaction is fast in comparison to pore diffusion. In this case reduction takes place mainly in a small reaction layer, moving gradually from the ore surface to the core during reduction. The layer has no sharp limits, but in practice the outer part of the ore body behind the moving layer consist almost exclusively of porous iron, and the inner part in front of the layer is unreduced ore. Under these circumstances Equation (78) is applicable, if the condition of an infinitely thin reaction layer as assumed in Equation (78) is replaced by the assumption of a layer of finite thickness. This was done by G. Bitsianes and coworker [55]. The ore model is shown in Figure 35 with a layer of thickness Δr, where the concentration shows a course as shown in the lower part of Figure 35. Equation (78) is altered by taking into account the layer thickness Δr and the inner surface of the layer. The original Equation (78) is expressed as

$$\frac{(p_0-p*)}{RT\cdot d_O}t = \frac{r_0}{k'}\left[1-(1-\Re)^{1/3}\right] + \frac{r_0^2}{6\,D_P}\left[1+2\,(1-\Re)-3(1-\Re)^{2/3}\right] \tag{78a}$$

while Bitsianes et al. published the following expression

$$\frac{\Delta c}{d_O}t = \frac{r_0}{k'\sigma\,\eta}\left[1-(1-\Re)^{1/3}\right] + \frac{r_0^2}{6\,D_P}\left[1+2\,(1-\Re)-3(1-\Re)^{2/3}\right] + \frac{r_0}{3\,\beta}\Re \tag{96}$$

The last term takes into account the mass transport through the outer gas boundary layer which is negligible as mentioned. The rest differs from Equation (78a) by the product $\sigma\eta$ in the first term on the right-hand side. This term takes into account the finite thickness of the reduction layer; η is the reduction effectivity v/v_{max}; σ is the internal surface area available in the reaction zone in addition to the area of the spherical shell expressed in terms of the total shell area:

$$\sigma = \Delta r \cdot a_i\left(1+\frac{\Delta r}{r}\right)+1 \tag{97}$$

where Δr is the thickness of the reaction layer; Δr must be taken from practical experience.

2.3.2. Reduction in the Liquid State

2.3.2.1. General

In the liquid state, the reduction of iron oxide is essentially limited to the reduction of FeO, because above 1400 °C, Fe_2O_3 has an oxygen partial pressure of decomposition of more than 1 bar, and also Fe_3O_4 is thermodynamically stable only under high $CO_2/(CO + CO_2)$ ratios which are normally not present in reduction processes for the liquid state. Thus, consideration is confined to the reduction of FeO from liquid FeO-containing slags. This reduction is an important process in the blast furnace and in smelting reduction reactors. The primary reducing agent can be either solid carbon (in the form of coke or

char), carbon dissolved in liquid iron, or carbon monoxide. However – in the liquid state just as in the solid state – the reduction itself is only possible with gas, preferably carbon monoxide. A direct reduction of FeO from a liquid slag by carbon is not possible, neither with solid carbon nor with carbon dissolved in liquid iron. This is because a gas layer of a carbon monoxide – carbon dioxide mixture forms immediately between the surface of the carbon containing phase and the surface of the FeO-containing slag in the moment when both surfaces come into contact. The reason is the great difference in oxygen potential between slag and the carbon-containing phase. Due to the gas layer, carbon monoxide can be the only direct reducing agent. The role of carbon is the production of carbon monoxide from carbon dioxide according to the Boudouard reaction. In combination with the FeO reduction ($CO + FeO \rightarrow Fe + CO_2$) the overall reaction equation $C + FeO \rightarrow Fe + CO$ results. An experimental study and a formal treatment of the kinetics of FeO reduction from a liquid slag requires, therefore, a separate consideration of the Boudouard kinetics and of the reduction kinetics under the conditions of the liquid state.

Laboratory experiments in which FeO is reduced from a slag by solid carbon or liquid carbon containing iron, give vigorous CO gas bubble evolution and thus, an uncontrolled reduction process, from which rate constants for the single steps cannot be obtained. Such studies give a qualitative impression of the behavior of the entire reduction system. But the results cannot be transferred to large industrial vessels as the vessel sizes, the degrees of bubble – melt dispersion, and the stirring conditions are different.

2.3.2.2. Microkinetics

In processes where liquid hot metal is produced, the reduction reaction proceeds formally according to Equation (30):

$$C + (FeO) \rightleftharpoons CO + [Fe] \tag{30}$$

Four different phases participate in this reaction, namely (1) liquid iron oxide containing slag, (2) solid carbon or carbon-saturated iron, (3) carbon monoxide, and (4) metallic iron as the reaction product. The product precipitates either in the solid or in the liquid state depending on the reaction temperature.

The existence of four different phases necessitates a reaction in three steps at different locations (see Fig. 38). On the left-hand side of Figure 38 a carbon-saturated iron droplet is shown, which may also be a carbon particle. The droplet is surrounded by the aforementioned gas layer which on its outer side adjoins the iron-oxide containing slag. (If coke is present instead of a carbon-containing droplet as is the case in the blast furnace, an irregularly shaped gas layer exists between the coke particle and the liquid slag).

Figure 38. Schematic representation of the reduction process in the slag

The following reactions occur:

At the interface between carbon-saturated iron droplet and gas:

$$CO_2 + C \rightleftharpoons 2\,CO \tag{98}$$

At the interface between gas and slag:

$$CO + FeO \rightleftharpoons CO_2 + (Fe) \tag{99}$$

where (Fe) denotes iron dissolved in the slag. In reality, iron exists in the slag in the form of di- and trivalent ions, Fe^{2+} and Fe^{3+}. Reaction (99) can, therefore, also be expressed as

$$CO + FeO + 2\,Fe^{3+} \rightleftharpoons CO_2 + 3\,Fe^{2+} \tag{100}$$

Both expressions are equivalent. The thermodynamic activity $a_{(Fe)}$ of dissolved iron in the slag is given by the equilibrium of the reaction $3\,Fe^{2+} \rightleftharpoons (Fe) + 2\,Fe^{3+}$. Hence, $a_{(Fe)}$ can be expressed as the temperature-dependent value:

$$a_{(Fe)} = K_{Fe^{2+}/Fe^{3+}} \frac{a^3_{Fe^{2+}}}{a^2_{Fe^{3+}}} \tag{101}$$

The $(a_{Fe^{2+}})^3/(a_{Fe^{3+}})^2$ ratio is a function of the $(\%\,Fe^{2+})/(\%\,Fe^{2+} + \%\,Fe^{3+})$ value in the slag.

If $a_{(\mathrm{Fe})} = 1$ in Equation (101), thermodynamic equilibrium exists between slag and liquid pure iron.

In the gas layer between droplet and slag surface (cf. Fig. 38 left), CO_2 and CO move countercurrent to one another.

The result of Equations (98) and (99) is the separation of 1 mol oxygen from the slag and 1 mol carbon from the carbon-containing droplet which form 1 mol of carbon monoxide, and the transfer of 2 mol trivalent iron and 1 mol FeO into 3 mol bivalent iron, which is equivalent to the formation of one mole dissolved iron in the slag. Because of the production of carbon monoxide, the gas layer around the iron droplet grows. At a certain critical layer size a bubble separates. This process takes place continuously so that carbon monoxide bubbles are periodically evolved.

As a consequence of Equation (99) or (100) the iron activity in the slag increases and eventually becomes unity, or the slag becomes supersaturated with dissolved iron. That means $a_{(\mathrm{Fe})} \geq 1$. The reaction product precipitates from the slag phase as metallic iron. This is similar to the situation in the reduction of solid wustite (see Figs. 32 A and B). Precipitation occurs at a different location than the one of oxygen separation from the slag. This is shown on the right-hand side of Figure 38. The reaction is expressed as

$$(\mathrm{Fe}) = [\mathrm{Fe}] \tag{102}$$

where [Fe] is metallic iron.

Iron precipitation may also take place at the gas – slag interface. Both possibilities correspond to those shown in Figures 32 A and B for the case of solid oxide.

Kinetic treatment of the reaction sequence presented in Figure 38 is carried out in two steps [56, 57]. The first one is a description of the microkinetics at the single bubble and droplet as shown in Figure 38. The second step is a summation of the microkinetic steps over the entire population of droplets and bubbles present in the reactor. Calculations of this type are known for conditions of smelting reduction. In this process carbon-saturated iron droplets are suspended in a slag in which the reduction occurs. Simultaneously, the slag dissolves iron oxide from the charged ore. Reduction rate of iron oxide and charging rate of ore are equivalent. Thus, in the steady state a constant iron oxide content exists in the slag.

According to Figure 38 the single microkinetic steps are:

1) Phase boundary reaction at the interface between carbon-saturated iron droplet and gas (Boudouard reaction), Equation (98)
2) CO and CO_2 transport in the surrounding gas layer
3) Phase boundary reaction at the interface between gas and slag, Equation (99)
4) Transport of iron oxide in the slag
5) Phase boundary reaction of iron precipitation, Equation (102)

Steps 2 and 5 may be neglected as it can be shown that they are fast [56, 57]. Thus, steps 1, 3, and 4 remain.

The forward reaction of step 1 is expressed as

$$-\left(\frac{\mathrm{d}n_{\mathrm{CO_2}}}{\mathrm{d}t}\right)_{\mathrm{G-M}} = A_{\mathrm{G-M}} k_{\mathrm{G-M}} \frac{P_{\mathrm{CO_2},i}}{RT} a_{[\mathrm{C}]} = A_{\mathrm{G-M}} k_{\mathrm{G-M}} \frac{P_{\mathrm{tot}} - P_{\mathrm{CO},i}}{RT} a_{[\mathrm{C}]} \tag{103}$$

where $A_{\mathrm{G-M}}$ is the gas – metal interface area, $k_{\mathrm{G-M}}$ the reaction rate constant, $P_{\mathrm{CO_2},i}$ and $P_{\mathrm{CO_2},i}$ the respective CO_2 and CO partial pressures at the interface, and $P_{\mathrm{tot}} = P_{\mathrm{CO_2},i} + P_{\mathrm{CO},i}$. P_{tot} is usually 1 bar. The back reaction needs not to be considered because the equilibrium lies almost completely on the side of carbon monoxide at the reaction temperature of 1300 – 1500 °C.

The phase boundary reaction at the gas – slag interface (step 3) is expressed as

$$\left(\frac{\mathrm{d}n_{\mathrm{CO_2}}}{\mathrm{d}t}\right)_{\mathrm{G-S}} = A_{\mathrm{G-S}} k_{\mathrm{G-S}} \left(\frac{P_{\mathrm{CO},i}}{RT} a_{\mathrm{FeO},i} - \frac{a_{(\mathrm{Fe})} P_{\mathrm{CO_2},i}}{K \cdot RT}\right) \tag{104}$$

Here, $A_{\mathrm{G-S}}$ and $k_{\mathrm{G-S}}$ are the reaction interface area and rate constant, respectively. The terms in parentheses express the difference in the driving force between the forward and the back reaction. $a_{\mathrm{FeO,i}}$ and $a_{(\mathrm{Fe})}$ are the respective iron oxide and iron activities in the slag at the interface, and K is the equilibrium constant

$$K = \frac{P_{\mathrm{CO_2},i} a_{(\mathrm{Fe})}}{P_{\mathrm{CO},i} a_{\mathrm{FeO},i}} \tag{105}$$

$a_{(\mathrm{Fe})}$ may be taken as unity over the entire slag as the precipitation reaction is fast.

Iron oxide transport in the slag (step 4) is expressed as

$$\left(\frac{\mathrm{d}n_{\mathrm{FeO}}}{\mathrm{d}t}\right)_{\mathrm{G-S}} = A_{\mathrm{G-S}}\beta_{\mathrm{G-S}}\left[c_{\mathrm{FeO}} - c_{\mathrm{FeO},i}\right] \tag{106}$$

where $\beta_{\mathrm{G-S}}$ is the mass transfer coefficient of iron oxide in the slag, and c_{FeO} and $c_{\mathrm{FeO,i}}$ the respective iron oxide concentrations in the bulk slag and at the gas – slag interface.

The molar carbon dioxide production after Equation (103), the molar carbon dioxide consumption after Equation (104), and the molar iron oxide flux after Equation (106) must be equal. With this continuity condition, Equations (103), (104), and (106) can be combined to yield a flux equation of the overall microkinetics. Attention must be paid in this context to the fact, that the bubble volume around the carbon-containing iron droplet increases gradually with periodical separation of a carbon monoxide bubble, which then rises in the slag. The interface area $A_{\mathrm{G-S}}$ oscillates therefore. It is useful to make calculations with a time average of the interface area $A_{\mathrm{G-S}}$. If the value α^2 is introduced, where α is the ratio of the droplet to the bubble radius, the bubble interface area $A_{\mathrm{G-S}}$ may be expressed by the droplet surface area $A_{\mathrm{G-M}}$ as $A_{\mathrm{G-S}} = \alpha^2 \cdot A_{\mathrm{G-M}}$. α is given by the critical diameter for bubble separation which depends on the carbon monoxide evolution rate and on the slag surface properties, primarily on the surface tension. With these considerations, it follows from Equations (103), (104), and (106):

$$\left(\frac{\mathrm{d}n_{\mathrm{FeO}}}{\mathrm{d}t}\right)_{\mathrm{G-S}} = A_{\mathrm{G-M}} \cdot \left[\frac{c_{\mathrm{FeO}}}{\frac{1}{K\,k_{\mathrm{G-M}}{}^{a}[\mathrm{C}]^{b}} + \frac{1}{\alpha^2 k_{\mathrm{G-S}}{}^{b}} + \frac{1}{\alpha^2 \beta_{\mathrm{G-S}}}}\right] \tag{107}$$

with

$$b = \frac{P_{\mathrm{CO},i}\, f_{\mathrm{FeO}} V_{\mathrm{S}}}{RT\, n_{\mathrm{tot}}}$$

Here, f_{FeO} is the activity coefficient of FeO in the slag, V_{S} the slag volume, and n_{tot} the number of moles in the slag.

2.3.2.2.1. Numerical Data for the Calculation of Microkinetics

First, the mass transfer coefficient in the slag $\beta_{\mathrm{G-S}}$ must be determined. The expression for spherical cap bubbles can be used as approximation in this case. The mass transfer coefficient is expressed as [58]

$$\beta_{\mathrm{G-S}} = 0.80 \cdot r_{\mathrm{eq}}^{-1/4} D^{1/2} g^{1/4} \tag{108}$$

where r_{eq} is the radius of the sphere of equal volume, g the acceleration due to gravity , and D the diffusion coefficient of FeO in liquid slags expressed by [57 – 63]

$$\ln D_{\mathrm{FeO}} = -14.335 - \frac{10716}{T} \tag{109}$$

Equation (109) is valid for low FeO-containing slags with, for example, 40 % CaO, 30 % SiO_2, 12 % Al_2O_3, 15 % MgO, and 1.5 – 5 % FeO. It is used up to ca. 30 % FeO. The rate constant of the Boudouard reaction $k_{\mathrm{G-M}}$ was frequently measured for pure iron – carbon alloys as well as for iron – carbon alloys with third elements dissolved in it. Sulfur is of special importance for the practice of iron ore reduction due to its strong effect on the reduction rate. The following expression by Sain and Belton [64] can be used for pure iron carbon alloys

$$k_{\mathrm{G-M}} = \exp\left(-\frac{11700}{T} + \ln T - 0.68\right) \tag{110}$$

with k in m/s. The influence of sulfur on the rate constant of Equation (110) is expressed by an extension of that equation as follows [65]:

$$k_{\mathrm{G-M}} = \exp\left(-\frac{11700}{T} + \ln T - 0.68\right) \cdot \frac{1+\kappa \cdot A \cdot Y_{\mathrm{S}}}{1+A \cdot Y_{\mathrm{S}}} \tag{111}$$

where κ is the part of the interface not covered with sulfur (= 0.014); A the adsorption coefficient of sulfur: log A = 3600/T + 0.57. Y_{S} the sulfur content in the iron melt (mass %). Equation (111) is valid for sulfur contents in liquid iron of 0 – 1.0 mass %. For 1773 K and 1873 K Equation (110) yields $k_{\mathrm{G-M}}$ = 1.22 m/s and $k_{\mathrm{G-M}}$ = 1.84 m/s, respectively. Equation (111) yields for 1873 K and 1 mass % sulfur: $k_{\mathrm{G-M}}$ = 0.032 m/s. That means that under otherwise equal conditions the reaction rate in the second case is roughly 50 times slower than in sulfur-free iron.

For the rate constant $k_{\mathrm{G-S}}$ of iron oxide reduction from a liquid iron oxide containing slag by carbon monoxide, Equation (112) was obtained from measurements between 1593 and 1723 K [66]

$$k_{\mathrm{G-S}} = T \cdot \exp\left(-\frac{16618}{T} - 0.11033\right) \tag{112}$$

with k in m/s. For 1773 K and 1873 K values of k_{G-S} = 0.135 m/s and k_{G-S} = 0.235 m/s are calculated.

The equilibrium constant of Equation (105) is expressed by [67]

$$\ln K = \frac{5946}{T} - 4.98 \tag{113}$$

Raoult's activity coefficient f_{FeO} is expressed by [68]

$$\begin{aligned} 8.314T \cdot \ln f_{FeO} = & -41840X_{SiO_2}^2 - 31380X_{CaO}^2 \\ & -41100X_{Al_2O_3}^2 + 33470X_{MgO}^2 \\ & +60670X_{SiO_2}X_{CaO} + 44770X_{SiO_2}X_{Al_2O_3} \\ & +58570X_{SiO_2}X_{MgO} + 82430X_{CaO}X_{Al_2O_3} \\ & +102510X_{CaO}X_{MgO} + 63600X_{Al_2O_3}X_{MgO} \\ & -8540 + 7.142T \end{aligned} \tag{114}$$

For the aforementioned slag, this yields f_{FeO} = 4.3. Raoult's activity coefficient of carbon in liquid iron can be expressed by [62]

$$f_{[C]} = \frac{1155 \cdot \exp\left(9.9\, X_C + 11.89\, X_S\right)}{T} \tag{115}$$

where X in Equations (114) and (115) denotes mole fractions.

With the presented data, the numerical values of the single reaction resistances in the denominator of Equation (107) can be determined. Table 14 shows the influence of sulfur on the rate constant k_{G-M} and the reciprocal resistance $K \cdot k_{G-M} \cdot b \cdot [a]_C$ for $[a]_C$= 1. The other two reciprocal resistances in Equation (107) $k_{G-S} \cdot b$ and β_{G-S}, both for α= 1. The mass transfer coefficient β depends on the droplet diameter. Two values, one for the smallest and the other for the largest class of droplet diameter are, therefore, presented. On the gas – slag interface the reaction rate constant $k_{G-S} \cdot b$ is a little smaller than the mass transfer coefficient β_{G-S}, which means that the main resistance at that interface lies in the phase boundary reaction.

The resistance on the gas – metal side is in the same order of magnitude as that on the gas – slag side only as long as the sulfur content is extremely low. Above [S] = 0.005 % already, the overall resistance lays mainly on the gas – metal side. α values higher than 1 increase the gas – slag reaction interface area and thus, the rate at that interface considerably, as the interface area is proportional to α^2. At very low sulfur contents, where the gas – metal and the gas – slag resistance are in the same order of magnitude, growing α will, therefore, accelerate the overall rate. When the sulfur contents are higher, the resistance at the gas – metal interface solely determines the overall rate, and hence, increasing α has no more an influence. Under these circumstances the gas – slag resistance is so small in comparison with the gas – metal resistance, that thermodynamic equilibrium establishes at the gas – slag interface.

Table 14. Numerical values of the single rate constant at 1500 °C in Equation (107) [57]

Sulfur content in the melt, mass%	k_{G-M}, m/s	$Kk_{G-M}b$, m/s
0.000	1.22	1.28×10^{-4}
0.001	0.88	9.22×10^{-5}
0.002	0.69	7.22×10^{-5}
0.005	0.42	4.41×10^{-5}
0.010	0.26	2.70×10^{-5}
0.020	0.15	1.59×10^{-5}
0.050	0.075	7.84×10^{-6}
0.100	0.047	4.89×10^{-6}
0.200	0.032	3.36×10^{-6}
0.500	0.023	2.43×10^{-6}

$\beta_{G-S,d_{min}}$ = 3.4 $\times 10^{-4}$ m/s; $\beta_{G-S,d_{max}}$ = 1.88 $\times 10^{-4}$ m/s; $k_{G-M}b$ = 0.72 $\times 10^{-4}$ m/s; d_{min} = 0.38 mm; d_{max} = 4.08 mm

2.3.2.2.2. Macrokinetics

Equation (107) describes the microkinetic reaction sequence at a single pair of reaction sites as shown in Figure 38. To describe the overall reduction rate, called macrokinetics, the number of such sites must be known, primarily the number of carbon-containing iron droplets generated per unit time. Iron droplets are ejected from the iron melt into the slag under the influence of rising bubbles of the stirring gas. The ejected droplets stay in the slag for a certain residence time depending on their sinking rates and on the conditions of slag motion. Together with the droplet evolution rate this yields the number of reaction sites present in the slag. Further, the droplets size distribution must be known. An example is given in Table 15.

Table 15. Droplet size distribution [70]

Droplet class j	Droplet diameter d_i, m	Volume portion v_i ,%
1	0.38×10^{-3}	6
2	0.75×10^{-3}	20
3	1.50×10^{-3}	30
4	3.56×10^{-3}	26
5	4.08×10^{-3}	18

The macrokinetic reaction rate $\dot{n}_{\mathrm{FeO}}$ which is reasonably related to the tonnage of the melt and thus, has the unity mol t^{-1} s^{-1}, is then given by amount of reduction $n_{\mathrm{FeO,D},i}$ at a single site in the mole (where i designates the droplet size class) and the number of droplets ejected into the melt per time and per tonne of melt. That yields

$$\dot{n}_{\mathrm{FeO}} = \sum\nolimits_i \frac{\dot{M}_{\mathrm{D}}\sigma_i}{\frac{1}{6}\pi d_{\mathrm{D},i}^3 \varrho_{\mathrm{D}}} \cdot n_{\mathrm{FeO,D},i} \tag{116}$$

where

$$n_{\mathrm{FeO,D},i} = \int_0^{t_{\mathrm{R},i}} \frac{\mathrm{d}n_{\mathrm{FeO}}}{\mathrm{d}t}\mathrm{d}t$$

$\mathrm{d}n_{\mathrm{FeO}}/\mathrm{d}t$ is defined in Equation (107) and $t_{\mathrm{R},i}$ is the droplets residence time in class i. In Equation (116) $\dot{M}_{\mathrm{D}}$ is the droplet formation rate in kg t^{-1} s^{-1}, σ_i the portion of droplets in class i, $d_{\mathrm{D},i}$ the diameter of droplets in class i, and ϱ_{D} the droplet density. Inserting Equation (107) into (116) yields

$$\dot{n}_{\mathrm{FeO}} = 6\,\dot{M}_{\mathrm{D}} \frac{c_{\mathrm{FeO}}}{\varrho_{\mathrm{D}}} \sum\nolimits_i \frac{\sigma_i}{d_{\mathrm{D},i}} \int_0^{t_{\mathrm{R},i}} \beta_{\mathrm{tot},i}\mathrm{d}t \tag{117}$$

with

$$\beta_{\mathrm{tot}} = \frac{1}{\frac{1}{K\,k_{\mathrm{G-M}}a_{[\mathrm{C}]b}} + \frac{1}{\alpha^2 k_{\mathrm{G-S}}b} + \frac{1}{\alpha^2\beta_{\mathrm{G-S}}}} \tag{118}$$

β_{tot} in Equations (116) and (117) is the overall microkinetic mass transfer coefficient which is identical with the reciprocal of the denominator in the brackets of Equation (107). β_{tot} is a function of the droplet carbon content, which varies with time.

Numerical calculation requires knowledge of the data for droplet behavior in Equation (117), i.e., drop formation rate and residence time. This knowledge is still meager in the case of iron oxide smelting reduction processes, but some details are found in the literature [68, 69].

Calculations with Equation (117) for a smelting reduction process [70] are shown in Figure 39. The figure shows the overall reduction rate of FeO as a function of the sulfur content in the iron droplet for a drop formation rate of 5 kg t^{-1} s^{-1} (in practice, the lower limit of this rate), for α = 1, and for the size distribution given in Table 15. The FeO content of the slag is the parameter. The reduction rate decreases strongly with rising sulfur content in the melt because the rate constant $k_{\mathrm{G-M}}$ depends on the melt sulfur content (see Table 14). The influence of α is weak under the conditions chosen. Growing FeO contents in the slag increase the driving force (see Eq. 117) and thus accelerate the reduction rate. The maximum possible reduction rate for smelting reduction conditions – which is limited by the gas throughput – lies between 3 and 5 mol Fe per tonne and second [71]. This rate requires 20 % FeO in the slag at 0.1 % S in the melt, and 30 % FeO in the slag at 0.2 % S in the melt. The necessary FeO contents are inversely proportional to the drop formation rate. Sulfur contents of 0.2 % are reported for smelting reduction conditions [72]. Published slag iron oxide contents in industrial smelting reduction units under steady-state process conditions and at 0.2 % S in the melt are 2 – 5 % [71]. This requires drop formation rates of the order of 50 kg t^{-1} s^{-1}.

2.3.3. Kinetics of Post-Combustion Heat Transfer

In smelting reduction processes post-combustion of process gases with transfer of the post-combustion heat back to the melt is one of the process steps (see Section 2.2.2).

The post-combusted gas has an oxidizing action on the liquid iron below it. Reoxidation of iron must, however, be avoided. Therefore, heat is preferably transferred between gas and melt with the slag as the transfer medium. Heat transfer is mainly accomplished by two methods. The first utilizes slag droplets which are ejected into the gas space and which, after a short residence time fall back into the melt. During their residence in the gas space the droplets are heated up by the gas and return to the melt with a higher temperature than before. The heat content corresponding to this higher temperature is the heat transferred. The second route of heat transfer utilizes post-combustion in a foamy slag. Heat is transferred from rising bubbles of the hot gas to the slag foam and from there by bath circulation to the melt. In the following, the mechanism of heat transfer according to the first route is described as an example [71].

Figure 39. FeO reduction rate at various droplet sulfur contents and at T = 1500 °C. FeO content of slag: 1.5 mass %; droplet formation rate: 10 kg t^{-1} s^{-1}

Post-combustion with Heat Transfer via Slag Droplets. For calculation of the post-combustion reaction and the accompanied heat transfer [71], the stoichiometry and the thermodynamics of the combustion reaction, the heat transfer process, and the heat flow balance must be considered. It is assumed that $\dot{m}$ mol CO evolve from the melt per unit of time and that $\dot{n}$ mol O_2 per unit of time are blown into the gas space above the melt for post-combustion. The value 2 $\dot{n}/\dot{m}$ is the theoretical post-combustion degree

$$PC_{\text{theor}} = 2\,\dot{n}\,/\,\dot{m} \tag{119}$$

Complete combustion is theoretically attained, if $\dot{n}/\dot{m}$ = 0.5. The real degree of combustion can be lower, especially at high temperature, as the combustion reaction is limited by thermal dissociation of CO_2. The degree of dissociation α is expressed as

$$\alpha = \frac{2x_{O_2}}{2x_{O_2}+x_{CO_2}} \tag{120}$$

where x is the molar fraction of the respective component in the gas.

Combustion in the gas space proceeds infinitely fast in comparison to heat transfer. Further, as an approximation it is assumed that the gas is completely mixed. Under these conditions the combustion reaction can be written as:

$$\begin{aligned}\dot{\mathrm{m}}\ \mathrm{CO}\,(\text{at}\,T_{\mathrm{M}}) + \dot{\mathrm{n}}\ \mathrm{O_2}\,(\text{at}\,298\,\mathrm{K}) &= \dot{\mathrm{q}}\ \mathrm{CO_2}\,(\text{at}\,T_{\mathrm{G}}) + \\ (\dot{\mathrm{m}} - \dot{\mathrm{q}}\ \mathrm{CO}\,(\text{at}\,T_{\mathrm{G}}) + \left(\dot{\mathrm{n}} - 1/2\,\dot{\mathrm{q}}\right)\mathrm{CO_2}\,(\text{at}\,T_{\mathrm{G}})\end{aligned} \tag{121}$$

where T_{M} is the bath temperature, T_{G} the gas temperature, and $\dot{\mathrm{q}}$ the number of moles CO_2 generated per unit of time.

The desired gas temperature follows from the heat balance in Equation (121). However, the reaction is incomplete due to CO_2 dissociation. The degree of dissociation depends on the gas temperature. Thus, there are two unknown quantities: the real gas temperature and the degree of dissociation. They have to be calculated by two equations, namely the above heat balance and the equilibrium of CO_2 dissociation. These considerations are valid for the adiabatic case. In reality, part of the post-combustion heat is transferred to the melt, which lowers the gas temperature. Therefore, a third equation describing the heat transfer rate is required in order to completely describe post-combustion with heat transfer. From Equation (121) and from the definitions given in Equations (119) and (120) the fractions of the gas components and the degree of dissociation can be calculated [70]. The obtained data can then be inserted into the equilibrium constant of CO_2 dissociation

$$K_{CO_2} = \frac{x_{CO}\cdot x_{O_2}^{1/2}}{x_{CO_2}} \tag{122}$$

yielding the following expression for the equilibrium constant as a function of the theoretical post-combustion degree and the degree of dissociation:

$$K_{CO_2} = \left[\frac{\alpha}{PC_{\text{theor}}+\alpha}\right]^{1/2} \cdot \frac{PC_{\text{theor}}-2(1-\alpha)}{2(1-\alpha)} \tag{123}$$

The equilibrium constant is a function of the gas temperature. That means, Equation (123) represents one of the two required relations between gas temperature and degree of CO_2 dissociation. A second relation between gas temperature and degree of dissociation follows from the heat flow balance derived from Eq. 121. This balance states that the difference between the enthalpy fluxes after and before post-combustion must be equal to the heat flow which is transferred per unit time from the post-combustion gas to the melt:

$$\begin{aligned}\dot{Q}_t = &-\dot{m}\cdot\left\{\left(H_{T_\mathrm{G}}-H_{T_\mathrm{M}}\right)_\mathrm{CO}\right\}\\ &-\dot{m}\cdot\left\{PC_\mathrm{theor}\,(1-\alpha)\left[\Delta\mathrm{H}^0_{\mathrm{CO}_2}-\Delta\mathrm{H}^0_\mathrm{CO}+\right.\right.\\ &\left.\left.\left(H_{T_\mathrm{G}}-H_{298}\right)_{\mathrm{CO}_2}-\left(H_{T_\mathrm{G}}-H_{298}\right)_\mathrm{CO}\right]\right\}\\ &-\dot{m}\cdot\left\{\tfrac{1}{2}PC_\mathrm{theor}\alpha\left(H_{T_\mathrm{G}}-H_{298}\right)_{\mathrm{O}_2}\right\}\end{aligned} \tag{124}$$

where ΔH^0 denotes enthalpies of formation and H_T enthalpies at temperature T (T_M = melt temperature, T_G = gas temperature). The first line describes the increase of enthalpy of CO when its temperature rises from T_M to T_G. The second line is the combustion heat at gas temperature, and the third the enthalpy required for heating the combustion oxygen from room to gas temperature (gas temperature always means the temperature after combustion). Equation (124) describes the heat balance of post-combustion for a given CO evolution rate from the melt $\dot{m}$ and for a given theoretical post-combustion degree PC_theor. With known heat flow $\dot{Q}_t$, Equations (123) and (124) together allow to determine the degree of dissociation α and the gas temperature T_G. The heat flow $\dot{Q}_t$ is expressed by

$$\dot{Q}_t = h_\mathrm{glob}\cdot A\cdot\left(T_\mathrm{G}-T_\mathrm{M}\right) \tag{125}$$

where A is the effective gas – melt interface area and h_glob the global heat transfer coefficient between gas and melt.

The product $h_\mathrm{glob}\cdot A$ follows from the mechanism of heat transfer via the slag droplets ejected into the gas space. The droplets have a certain size distribution and must, therefore, be divided into a number of classes i. Each droplet in the same size class is heated up in the same way. The heat flow to a single droplet in class i is given as

$$\dot{Q}_{\mathrm{D},i} = \pi\, d^2_{\mathrm{D},i}\cdot h_i\left(T_\mathrm{G}-T_\mathrm{D}\right) \tag{126}$$

where $d_{\mathrm{D},i}$ is the droplet diameter, h_i the heat transfer coefficient in class i involving convective and radiative components, T_G the gas temperature, and T_D the droplet temperature. The heat transfer coefficient depends on temperature. As an approximation, this dependence is neglected in the following. Details for determination of the heat transfer coefficient at a single sphere in a surrounding fluid can be found in the literature [50, 70].

The heat flow $\dot{Q}_{\mathrm{D},i}$ is identical with the heat taken up by the droplet. It is given as

$$\dot{Q}_{\mathrm{D},i} = \frac{1}{6}\pi\, d_i^3\cdot C_\mathrm{P}\,\varrho_\mathrm{D}\,\frac{\mathrm{d}T_{\mathrm{D},i}}{\mathrm{d}t} \tag{127}$$

where C_P is the heat capacity, and ϱ the density. Equating (126) and (127) yields after integration with $T_\mathrm{D} = T_\mathrm{M}$ at $t = 0$

$$\frac{T_\mathrm{D}-T_\mathrm{M}}{T_\mathrm{G}-T_\mathrm{M}} = 1-\exp\left(-\frac{6h}{C_\mathrm{P}\,\varrho d_{\mathrm{D},i}}t\right) \tag{128}$$

The total heat transfer from gas to melt via the droplets is given by

$$\dot{Q}_t = C_\mathrm{P}\sum\nolimits_i \dot{M}_{\mathrm{D},i}\sigma_i\left(T_{\mathrm{D},i,\mathrm{final}}-T_\mathrm{M}\right) \tag{129}$$

$T_{\mathrm{D},i,\mathrm{final}}$ is the temperature which the droplets have in the moment when they fall back into the melt, i.e., at their residence time t_r. Its value is obtained from Equation (128) with $t = t_\mathrm{r}$. This yields

$$\dot{Q}_t = C_\mathrm{P}\sum\nolimits_i \dot{M}_{\mathrm{D},i}\sigma_i\eta_i\left(T_\mathrm{G}-T_\mathrm{M}\right) \tag{130}$$

where σ_i is the fraction of droplets in class i, and η_i the efficiency of heat transfer via droplets of class i:

$$\eta_i = 1-\exp\left(-\frac{6h_i}{C_\mathrm{P}\,\varrho d_{\mathrm{D},i}}t_{\mathrm{r},i}\right) \tag{131}$$

Equation (130) in connection with (131) allows to determine the heat flow $\dot{Q}_t$ which is identical with $\dot{Q}_t$ in Equation (124). Thus, the post-combustion reaction with heat transfer can be calculated, if the droplet size distribution is known. This distribution function obeys the Rosin – Rammler – Sperling function R_V, which gives the mass percentage on a sieve with a mesh diameter d:

$$R_\mathrm{v} = 100\exp\left[-\left(\frac{d}{d'}\right)^n\right] \tag{132}$$

Figure 40. A) Gas temperature as a function of the theoretical post-combustion degree with the drop formation rate as the parameter;
B) Degree of CO_2 dissociation as a function of the theoretical post-combustion degree with the drop formation rate as the parameter;
C) Heat transfer efficiency as a function of the theoretical post-combustion degree with the drop formation rate as the parameter

The parameters d' and n were $d' = 3$ mm, $n = 1.3$ [70].

Figures 40 A – C show for various total slag drop formation rates $\dot{M}_{\mathrm{D,S}}$ the gas temperature, the degree of CO_2 dissociation, and the global heat transfer efficiency $\dot{Q}_t / \dot{Q}_{\mathrm{ideal}}$ (with $\dot{Q}_{\mathrm{ideal}}$ the heat transfer rate if $T_{\mathrm{G}} = T_{\mathrm{M}}$), as functions of the theoretical post-combustion degree PC_{theor}. It can be seen that the temperature increases with rising post-combustion degree. At low drop formation rates, where $\dot{M}_{\mathrm{D,S}}$ is almost zero, temperatures of up to 2800 °C are found. At high post-combustion degrees the temperature curves are getting increasingly horizontal, because the CO_2 dissociation degree becomes remarkable. The degree of dissociation reaches up to 50 %, and combustion then almost ceases. The temperatures remain lower at high than at low drop formation rates, because heat transfer is stronger in the former case. Simultaneously, CO_2 dissociation decreases. Below 1700 °C, dissociation is nearly zero at all post-combustion degrees. Heat transfer efficiencies for drop formation rates of 400 – 600 kg/s are ca. 80 %. At high post-combustion degrees where temperatures of 2000 °C are attained, the heat transfer efficiency decreases due to CO_2 dissociation.

2.4. Classification of Reduction Processes

For the pyrometallurgical reduction in the solid state iron ore must be heated to 450 – 1100 °C, for the reduction from an oxide melt temperatures of about 1400 °C are required. The reduction is a heterogeneous reaction, solid oxide is reduced by a gas, liquid oxide by a gas or a solid.

The choice of a particular reduction process usually also determines the subsequent steelmaking process. The iron produced by the reduction can have almost any combination of properties as shown in lists I and II:

I
1) solid
   - low in gangue content
   - high in gangue content
2) liquid

II
1) low in carbon content
2) high in carbon content

Many proposals have been advanced to achieve the reduction of iron on a technological scale.

Table 16. Classification of the technologically important reduction processes

Shaft furnace processes	
Blast furnace process	hot metal
Midrex process	solid sponge iron
HyL-III process	solid sponge iron
Rotary kiln processes	
SL/RN process	solid sponge iron
Krupp Codir process	solid sponge iron
ACCAR process	solid sponge iron
Fluidized-bed processes	
Tisco process	briquetted iron powder
Fior process	briquetted iron powder
Iron carbide process	briquetted iron powder
Circored process	briquetted iron powder
Discontinuous processes	
HyL-I process	solid sponge iron
Smelting reduction processes	
HIsmelt process	hot metal
DIOS process	hot metal
AISE initiative	hot metal
Electro-reduction processes	
Jupiter process	hot metal
Plasma-smelt process	hot metal

The *continuous processes* can be grouped according to the direction of the relative movement of the heat and the reducing gas flows versus the flow of the ore. The most important group of processes in which both heat and reducing gas flow countercurrently to the ore are the shaft furnaces and some fluidized-bed processes. Processes with countercurrent heat flow and crossflow of reducing gases use rotary kilns. Here, the reducing gas is liberated from the solid carbon contained in the burden and flows perpendicular to the direction of flow of the ore through the burden. Crossflow of heat and reducing gas is characteristic for most fluidized beds. Smelting reduction processes are mostly carried out in bath reactors. With few exceptions these processes usually constitute the final reduction stage of a two-stage process, the first stage being prereduction in the solid state. In smelting reduction the process gases are frequently post-combusted. The so-called *electro-reduction processes* occupy a special place in the family of smelting reduction processes because with them, reduction is possible with energy utilization near

100 %. Reduction processes presently used or under development and expected to be in use in the future on a large technological scale are summarized in Table 16.

2.4.1. Limiting Conditions for the Reduction in Shaft Furnaces

Gas Throughput. A prerequisite for the smooth operation of a shaft furnace is a good gas permeability of the burden. This requires that the various burden constituents have an average grain diameter that is as large as possible. There is, however, an upper limit to the grain diameter because the rate of heating and reduction decreases with increasing grain diameter. The choice of an optimum particle size must be based on a compromise.

The pressure drop of the gas characterizes the gas permeability of the burden in a shaft furnace. For turbulent flow through a burden consisting of equal grains the pressure drop ΔP is given by

$$\Delta \mathrm{P} = \frac{\mathrm{C_D}\,\varrho\,(1-\varepsilon)\,\mathrm{u}^2\mathrm{L}}{\varepsilon^3 \Phi \mathrm{d}} \tag{133}$$

where C_D is the drag coefficient which is a function of the Reynolds number; ϱ the density of the gas, ε the void fraction in the burden of randomly distributed particles, u the superficial gas velocity; L is the height of the burden; Φ the shape factor of the ore grains (0.6 to 1 for spheres) and d the grain diameter.

For a burden consisting of spheres of equal size, the random void fraction ε cannot be < 0.42 [50]. The effect of the void fraction on the pressure drop is, therefore, small. This is valid for all particle sizes as the void fraction of uniformly sized grains is always independent of the size itself. For a burden consisting of grains of various sizes the void fraction is in any case < 0.42, which means that the pressure drop increases. For small values of ε the effect of the cubic term in Equation (133) is large but the term $(1 - \varepsilon)$ has little influence. Moreover, the drag coefficient is not only a function of the Reynolds number but also of the grain size distribution. It is particularly sensitive to the presence of fines.

The relationship between drag coefficient C_D, Reynolds number Re and void percentage ε is given by the expanded version of the Karman – Kozeny equation [74]

$$C_\mathrm{D} = \left(\frac{160}{Re} + 3.1\,Re^{0.1}\right)\left(\frac{\varepsilon_\mathrm{k}}{\varepsilon_\mathrm{m}}\right)^{0.75} \tag{134}$$

where ε_k is the void fraction of the grain size fraction with the smallest grain diameter, ε_m is the void fraction of the mixture and

$$Re = \frac{\varrho u d \Phi}{\eta\,(1-\varepsilon)} \tag{135}$$

where η is the kinematic viscosity of the gas. The *pressure drop* in a burden consisting of spheres of various sizes can be calculated from Equation (133) by making use of Equation (134) for C_D and by substituting an equivalent grain diameter d_e for the grain diameter d, where d_e is given by

$$d_\mathrm{e} = \frac{1}{\sum\limits_{i=1}^{n} \frac{c_i}{d_i}} \tag{136}$$

d_i being the grain diameter of the grain size fraction i and c_i the volume percentage of fraction i.

The effects of the grain size and the relative quantity of fine grains under conditions approaching those in the blast furnace are shown in Figure 41. Depending on the ratio between the diameters of large and small grains, a fine grain fraction of even 10 % causes a pressure drop that is 4 to 7 times that of a burden consisting of equal sized grains.

Figure 41. Relative pressure drop in burdens consisting of various grain sizes as a function of the fraction of fines [74] Δp = pressure drop in the presence of fines; Δp_0 = pressure drop without fines (diameter of shaft furnace = 7.0 m; quantity of cold blast = 90 000 m^3(STP)/h; $\varepsilon_\mathrm{k} = \varepsilon_\mathrm{g} = 0.38$ Properties of the air: temperature θ = 1000 °C, density ϱ = 0.265×10^{-3} g/cm^3, kinematic viscosity ν = 1.792 cm^2/s

Figure 42. Stability limits of burden layers at 800 °C; burden consists of spheres of equal size; $\varepsilon = 0.4$ [19]
Bulk density of the burden grains: a) $\varrho_S = 5.0$ g/cm^3; b) $\varrho_S = 5.0$ g/cm^3; c) $\varrho_S = 2.0$ g/cm^3; d) $\varrho_S = 1.0$ g/cm; Flowing gas: a) Hydrogen; b, c, d) Carbon monoxide – nitrogen mixtures

Under practical conditions the fines often preferentially collect in regions where the resistance is high and, hence, the gas flow rate is low. This causes a further increase in the resistance. Finally, this condition may lead to the so-called "channeling", a situation in which the gas flows at a high rate through individual channels and is hardly being utilized, while it no longer flows through the rest of the burden. Thus, the burden destined for shaft reduction furnaces is carefully prepared by screening, comminution of large grains and agglomeration of fines to give a narrow particle size distribution. Abrasion strength, crushing strength, and swelling behavior have to meet stringent requirements.

A burden consisting of grains of a given diameter possesses a maximum limit of the gas flow rate through it (stability limit of the stationary burden). Above that limit the burden changes into a fluidized bed. The limit is determined by the requirement, that the pressure drop along the burden height remains lower than the weight of the burden. The pressure drop may be calculated from Equation (133) by using the value for C_D from Equation (134) for a burden consisting of equal grains and *Re* from Equation (135). Then, the thus calculated pressure drop per unit of burden height $\Delta p/L$ is set equal to the weight of the burden per unit of volume $(1-\varepsilon)\varrho_S\, g$; where ϱ is the bulk density of the burden, and g the gravitational acceleration. The obtained equation is resolved with respect to the gas velocity u, which is the desired critical velocity u_{crit} [214].

$$u_{crit} = \frac{0.54\left(\varrho_S g \varepsilon^3\right)^{0.526}}{[(1-\varepsilon)\,\eta]^{0.0526}} \frac{(d\Phi)^{0.579}}{\varrho_G^{0.473}} \tag{137}$$

Here, ϱ_G is the gas density.

The calculated critical flow rate for burdens consisting of grains of equal size is shown in Figure 42 as a function of the grain diameter d, the type of gas, and the density of the solid. Dense iron ore has a density of ca. 5 g/cm^3, coke ca. 0.9 g/cm^3. The maximum superficial velocity in the blast furnace is ca. 3 m/s and the Reynolds numbers are between 1000 and 3000 (see Fig. 43).

Figure 43. Nusselt number Nu' as a function of Reynolds number Re'' [75] A) For sinter (o), ore (□) and coke (△)
A) Relation valid for spheres [74]
B) For the following pellet burdens

Pellet	Diameter, cm	Porosity ε
△	1.1	0.528
▲		0.458
□	2.5	0.464
■		0.381
○	3.0	0.498
⬢		0.435

To increase the gas throughput of a shaft furnace, despite the fact that the stability limit has been reached, the gas pressure should be increased. The mass gas flow rate does not increase in proportion to the increase in pressure because the critical flow rate is lower at higher pressures.

When the pressure is increased from 0.1 MPa to 0.4 MPa, the process remains operating at the stability limit, and the mass throughput of the gas is only doubled.

Heat Transfer. The experimentally determined heat transfer between gas and burden is shown in Figure 43 A for sinter, ore, and coke and in Figure 43 B for pellets [75]. The heat transfer is depicted in the form of a relation between the expanded Nusselt number

$$N\,u\prime = \frac{\alpha_{\Sigma} d}{\lambda} \frac{\varepsilon}{(1-\varepsilon)}$$

and the expanded Reynolds number

$$Re'' = Re \frac{1}{1-\varepsilon}$$

Here, α_{Σ} is the overall heat transfer coefficient which reflects transition of heat to the total volume of a solid grain contained in the burden, i.e., it includes heat conduction in the solid. α_{Σ} increases with decreasing grain diameter and porosity and with increasing Reynolds number [75]. Curve a in Figure 43 describes heat transfer to solid spheres [74]. It can be seen from Figure 43 that the heat transfer between gas and sinter is the best and better than to solid spheres, while the heat transfer to ore, coke, and pellets roughly agrees with that to solid spheres and does not show any difference among the different types of burden. The Nusselt number, i.e., the heat transfer coefficient increases with increasing Reynolds number, i.e., increasing superficial gas velocity and decreasing grain diameter.

The high heat transfer coefficient for sinter in Figure 43 A result from the lower density of sinter in comparison with the other materials (see Fig. 44). Lower density means that less heat is taken up per mass unit. This yields an apparently higher heat conductivity in the solid and hence a higher α_{Σ}.

To minimize the time for *heating the burden* it must be kept in mind that the heat flux

$$Q = \alpha_{\Sigma} F\,\Delta \mathrm{T}$$

depends not only on the heat transfer coefficient α_{Σ} but also on the area per volume F available for the transfer of heat. This area increases with decreasing grain radius according to $F \sim 1/r$. The temperature difference ΔT at the gas – solid interface increases with increasing thermal conductivity of the solid because the accumulation of heat on the surface of the solid decreases with higher heat conductivity. The heat conductivities of various burden components are shown in Figure 45. The heat conductivity of coke is relatively poor and in the blast furnace its grains are relatively large. Hence, in the blast furnace coke is heated at a slower rate than ore. In general, this is desirable in order to achieve the suppression of the coke gasification according to the Boudouard reaction.

Figure 44. Relation between drag coefficient C_{D} and the Reynolds number Re'' for burdens consisting of various materials;
Average grain diameter d_{m}, cm: a) Smooth pellets d_{m} = 1.98; b) Sinter d_{m} = 1.76; c) Sinter d_{m}=1.72; d) Ore d_{m} = 2.18; e) Coke d_{m} = 1.79

Figure 45. Heat conductivity of materials charged to the blast furnace [76]

From the temperature and Reynolds number distribution over the dimensionless burden height x/H (x = distance from the tuyere plane, H = burden height measured from the tuyere plane) (Fig. 46), it may be seen that a difference in temperature distribution in the center of the burden only slightly affects the Reynolds number and that the Reynolds numbers in the upper part of the shaft increase because the viscosity of the gas decreases with decreasing temperature. The high Reynolds numbers cause a rapid heating in the preheat zone of the furnace (see Figs. 43, 44, 45).

Figure 46. Profiles of the quantity of stack gas (left), its temperature and Reynolds number (right) in the column of a blast furnace burden [77]
x = distance to tuyere plane; H = burden height from the tuyere plane; V = quantity of blast = 90 000 m^3(STP)/h; V_S = quantity of stack gas; $Re = Re_0\ \eta_0/\eta$ with $Re_0 = u_0\ d/\nu_S$; η_0 = gas viscosity at 25°C; η = gas viscosity at shaft gas temperature; d = 21 mm; $\nu_0 = 1.33\times10^{-5}$ m^2/s; $u_0 = u_0{}^*/\varepsilon$; $\varepsilon = 0.33$; $u_0{}^* = V_S/A$; A = area of stack

Mass Transfer. The mass transfer between the gaseous phases and the ore has been discussed extensively in Section 2.3.1.2. Here, attention is drawn once more to the desirability of rapidly increasing the temperature to minimize the time needed for the exchange of matter. In addition, the burden should consist of grains with a radius so small that the reduction rate becomes independent of the grain radius.

2.4.2. Limiting Conditions for the Reduction in Rotary Kilns

The ore – coal mixture in a rotary kiln is usually heated countercurrently by hot combustion gases. The fuel consists primarily of carbon monoxide that is evolved from the burden, partly of hydrocarbons axially injected from the exit end. Carbon monoxide is combusted with air that is injected via tuyeres mounted in the drum. In the first section of the furnace (about one-third of the total volume in small furnaces, more than half of the total volume in large furnaces) the burden is heated to ca. 800 °C. Here, no oxygen is removed from the ore, except whenever high volatile coals are used. At higher temperatures carbon dioxide from the heating gas reacts with carbon to produce carbon monoxide according to the Boudouard reaction. Carbon monoxide reacts with the oxygen in the ore to regenerate carbon dioxide which, in turn, reacts with carbon to produce carbon monoxide, etc. During the Boudouard reaction the number of moles in the gas doubles, resulting in an outward gas flow from the coal – ore burden inside the kiln. The gas leaving the burden is a mixture of carbon monoxide and carbon dioxide with a $CO:CO_2$ ratio of roughly 80 : 20 and a certain amount of hydrogen and water vapor. The exact gas composition depends on the relative reactivities of the coal and the ore, whereby the carbon monoxide content grows with increasing coal reactivity. Figure 47 shows as an example the development of the gas and burden temperature and the degree of reduction for some ores in a 14 m rotary kiln [19]. It can be seen that the preheating zone where the burden has still a temperature below 800 °C, extends over ca. 40 % and the reduction zone over ca. 60 % of the kiln length. The final burden temperature is ca. 1100 °C.

The overall reduction reaction can approximately be written as

$$n\,C + FeO_n \rightarrow n\,CO + Fe \quad \Delta H = +164.1\ kJ/mol\ Fe \quad (138)$$

although the reduction proceeds via the gaseous phase.

Figure 47. Degree of reduction and temperature profiles in rotary kilns [19]
Temperature: (a) in the furnace, (b) in the burden; Degree of reduction:(c) of Venezuela ore, (d) of Itabira ore, (e) of Bomi-Hill ore

The overall reaction, Equation (138), proceeds inside the burden and is strongly endothermic. The developed carbon monoxide is combusted over the burden where the required heat is liberated. (This is the oldest application of post-combustion in metallurgical processes). The heat is transferred from the gas to the burden directly and through the hot wall which serves as heat reservoir. The heat is always regenerated and the transfer occurs to a considerable degree by back-radiation from the hot wall when the wall rotates under the burden. The degree of reoxidation of the reduced iron by the oxidizing flame gases is only small because a layer of burning carbon monoxide at the burden surface shields the iron from direct contact with the gas. Because heat transfer in this zone is rather intense, heat transfer is not the rate determining step here. Rather, the rate of the reduction reaction limits the productivity in the reduction zone.

The reduction rate v_1 and the coal gasification rate v_2 may be approximated by [79]:

$$v_1 = -\frac{\mathrm{d}O}{\mathrm{d}t} k_1 O_\mathrm{V} \left(c - *c_1\right) \tag{139}$$

$$v_2 = -\frac{\mathrm{d}C}{\mathrm{d}t} = k_2 M_\mathrm{C} \left(*c_2 - c\right) \tag{140}$$

Here, O_v and M_c are the quantities of oxygen in the ore and carbon present at time t, both with respect to the ore volume, $*c_1$ is the carbon dioxide concentration in equilibrium with the iron oxide present (Fig. 14), $*c_2$ is the carbon dioxide concentration at the prevailing temperature and in equilibrium with carbon according to the Boudouard reaction (Fig. 14), c is the actual carbon dioxide concentration at a given location inside the burden. The reaction rate constants k_1 and k_2 correspond to the volumetric rate constants k_v and k_eff in Sections 2.3.1.1 and 2.3.1.2.

In the steady state of the process, $v_2 = v_1$. Then, from Equations (139) and (140) an expression for the overall reaction rate can be derived:

$$v = v_1 = v_2 = M_\mathrm{C} \left(*c_2 - *c_1\right) \frac{1}{\frac{M_\mathrm{C}}{O_\mathrm{V}} \cdot \frac{1}{k_1} + \frac{1}{k_2}} \tag{141}$$

The rate increases when the term $(*c_2 - *c_1)$ increases. According to Figure 14, this term is maximum at ca. 1000 °C. Furthermore, v_2 is affected by k_1 as well as by k_2. As mentioned above, the steady-state gas composition in the burden lies the more on the CO side, the higher the ratio k_2/k_1. In the Baur – Glaessner diagram depicted in Figure 48 measured gas compositions of the burden for the reduction with reducing agents of different reactivity k_2 are shown as a function of temperature. One agent was low temperature lignite coke, the other coke breeze. Curves a and b show the measured gas compositions. For steady state production conditions, v yields directly the production rate λ in kg Fe per cubic meter burden volume and time.

Figure 48. Gas composition inside the burden of a rotary kiln as a function of the temperature projected on a Baur – Glaessner diagram [19]
a) Reduction with low temperature lignite coke; b) Reduction with coke breeze

Whenever low temperature lignite coke with a value of k_2 that is in excess of that for coke breeze is used, the reduction at 1000 °C proceeds with higher CO content in the gas than in the case of coke breeze.

Factors Influencing the Kiln Productivity. The reduction reaction in the rotary kiln proceeds preferably above ca. 800 °C, depending on the char reactivity. Therefore, the burden initially passes a preheating zone in the kiln where the burden is heated from room temperature to 800 °C. In this zone heat is transferred to the burden from the combusted furnace gas coming from the reduction zone. Heat is transferred mainly by convection in the gas space and in the burden, and by regeneration via the rotating furnace wall, whereas radiation is weak below 800 °C, which is in contrast to the reduction zone. Due to the absence of noticeable radiation, heat transfer per unit of kiln length is less intense in the preheating than in the reduction zone and is, thus, rate determining in the former. The total kiln length is the sum of the preheating and the reduction zone length. Under steady-state conditions the consumption of heat per time for preheating the burden to the reduction temperature must be equivalent to the iron production in the reduction zone. The production P in t Fe/h can therefore be expressed either by the preheating or by the reduction process. With a few simplifications, this can be expressed as follows:

1) By the preheating process:

$$P = \frac{1}{Q}\bar{S}_{\mathrm{P}} l_{\mathrm{P}} \alpha_{\mathrm{P}} \left(\Delta\,\bar{\vartheta}\right) \tag{142}$$

2) By the reduction process:

$$P = \lambda l_{\mathrm{R}} \frac{\pi}{4} d^2 \bar{\vartheta}_{\mathrm{R}} \tag{143}$$

In Equation (142), Q is the heat demand in kJ per tonne Fe between 25 and 800 °C in the preheating zone, $\bar{S}_{\mathrm{P}}$ the average length of the secant which the burden surface forms with the inner kiln wall surface in the preheating zone in a cross section, l_{P} the length of the preheating zone. α_{P} the overall heat transfer coefficient in kJ m^{-2} h^{-1} K^{-1} between heating gas and burden in the preheating zone, $(\Delta\bar{\vartheta})_{\mathrm{P}}$ the average temperature difference between gas and bulk burden in the preheating zone. $\bar{S}_{\mathrm{P}} l_{\mathrm{P}}$ is the heat transfer area for preheating. The heat flux $\alpha_{\mathrm{P}}(\Delta\bar{\vartheta})_{\mathrm{P}}$ is estimated as being 50 kW/m^2 for a gas temperature of 500 °C and 230 kW/m^2 for 1000 °C [19]. In Equation (143), λ is the volume-specific reduction rate in t Fe m^{-3}h^{-1} in the reduction zone, l_{R} the length of the reduction zone, d the inner kiln diameter, and $\bar{\vartheta}_{\mathrm{R}}$ the average filling degree in the reduction zone. The secant $\bar{S}_{\mathrm{P}}$ in Equation (142) can be expressed by the product of the inner kiln diameter and a function of the filling degree $\bar{\varphi}_{\mathrm{P}}$: $\bar{S}_{\mathrm{P}} = d \cdot f(\bar{\varphi}_{\mathrm{P}})$.

Taking this into account and equating Equations (142) and (143) for the steady-state production, yields the length of the reduction zone as a function of the kiln length and the main characteristic process parameters used in Equations (142) and (143):

$$l_{\mathrm{R}} = \frac{l_{\mathrm{klin}}}{1 + \frac{\bar{\varphi}_{\mathrm{R}}}{f(\bar{\varphi}_{\mathrm{P}})} \frac{d}{C}} \tag{144}$$

with

$$C = \frac{\pi}{4} \frac{\bar{\alpha}_{\mathrm{P}} \left(\Delta\,\bar{\vartheta}\right)_{\mathrm{P}}}{Q \cdot \lambda} \tag{145}$$

C contains the characteristic process data. It has the dimension of a length and is, multiplied by $4/\pi$, the ratio of the volume of the reduction zone to the area of the preheating zone, which establishes, whenever the process runs in the steady-state. The factor C mainly depends on the burden properties, especially the reactivities of coal and ore, and on the conditions of post-combustion and heat transfer above the burden. Inserting Equation (144) in (143) with $\pi/4 \cdot d^2 \cdot l_{\mathrm{kiln}} = V_{\mathrm{kiln}}$ yields the volume-specific production rate

$$\left(\frac{P}{V}\right)_{\mathrm{klin}} = \lambda \cdot \frac{1}{\frac{1}{\bar{\varphi}_{\mathrm{R}}} + \frac{d}{C} \frac{1}{f(\bar{\varphi}_{\mathrm{P}})}} \tag{146}$$

as a function of the kiln length, of the factor C, and of the filling degrees in the preheating and in the reduction zone. The important consequence of Equation (146) is that the volume-specific production rate decreases with increasing kiln diameter d. The reason is that the heat demand is volume-specific, i.e., proportional to d^3, while heat transfer grows only with d^2. As a consequence, the fraction of the preheating zone length in the total kiln length increases with increasing d. For very large d only preheating is

rate determining, whereas for very small d only reduction is rate determining.

The following consideration illustrates the requirement of the heat transfer area [212]. Preheating of a typical charge for the production of sponge iron (1430 kg Fe_2O_3, 500 kg C, 100 kg gangue, 100 kg moisture, all per tonne Fe) to a temperature of 800 °C requires a heat quantity Q of $1650 \cdot 10^3$ kJ/t Fe. To transfer this heat to the charge, the latter must have a surface area $A_P = \bar{S}_P l_P$ (cf. Eq. 142) in the preheating zone of

$$A_P = \frac{P \cdot Q}{24q} \tag{147}$$

where q is the average heat flux (kJ m^{-2} h^{-1}). Division of A_P by the production rate P yields

$$a_P = \frac{A_P}{P} = \frac{Q}{24q} \tag{148}$$

where a_P is the specific heat transfer area per tonne of iron and day. Figure 49 shows the relation between the average heat flux and the necessary specific heat transfer area.

Figure 49. Required surface area of the burden in the preheating zone, a_P (m^2 per tonne Fe and day)) for the production of 1 t sponge iron per hour, as a function of the heat flux [212]. Burden per tonne of iron: 1430 kg Fe_2O_3, 500 kg C, 100 kg gangue, 100 kg water

The overall heat flow for a certain production rate in the rotary kiln is expressed by [79]

$$\dot{Q} = m\bar{c}_P \frac{dT_m}{dt} + \Delta H \cdot v \tag{149}$$

where m is the mass of the burden, $\bar{c}_P$ the average heat capacity of the burden, T_m the average burden temperature, ΔH the reaction enthalpy of the reduction reaction (143), v the reduction rate. As the reaction enthalpy is almost completely consumed by the coal gasification reaction, the value of ΔH for that reaction can be used and correspondingly the rate v_2 of that reaction.

2.4.3. Limiting Conditions for the Reduction in Fluidized Beds

The *reduction rate* of very small ore particles with diameters between 50 and 150 μm is significantly higher than that of the ore particles that are used in shaft furnaces or in rotary kilns. The reduction rate of very small particles in fluidized-bed reactors (→ Fluidized-Bed Reactors) is shown in Figure 50. The flow diagram of fluidized beds for iron powders fluidized with carbon monoxide or hydrogen is shown in Figure 51.

Figure 50. Degree of reduction as a function of time for various temperatures and particle diameters during reduction in hydrogen [19]

The *rate of heat transfer* from gas to solid is also high in a fluidized bed. This is the result of the large effective interfacial area between the phases but also of the high heat transfer coefficients in a fluidized bed [19].

Fluidized beds have a series of disadvantages, which prevented their broad utilization in the past:

Figure 51. Flow diagram of a fluidized bed for iron ore powder ($\varrho = 5$ g/cm^3) at 700 °C [19]

1) Almost completely reduced material, which requires a reducing gas with a high percentage of a reducing agent for further reduction, is continually mixed with unreduced ore that does not require as high a percentage of reducing agent. This results in poor gas utilization and requires the recirculation of large quantities of gas. In technical installations fluidized-bed reactors are, therefore, put in series; this leads to a certain degree of countercurrent reaction.
2) As can be seen from Figure 51, each grain size requires a critical gas flow rate for a stable fluidized bed. In practice, the charge consists of a mixture of particles of different sizes. Therefore, at a certain gas flow rate, particles smaller than those corresponding to the critical flow rate are blown out, and larger particles fall down. The size distribution function must be small for a stable fluidized bed.
3) The tendency of freshly reduced iron particles to sintering, so-called *sticking,* is troublesome. As soon as the sintering process has started in any given location, it spreads to the entire fluidized bed in a few seconds. The result is a uniformly porous body that attaches itself to the perforated bottom plate of the reactor. The gas flows through a few channels inside the body and the reduction is greatly impeded.

The first two disadvantages, i.e., poor gas utilization and instability of the fluidized bed can be overcome by use of the circulating fluidized bed described in Section 2.6.3. The third is more or less successfully governed by the addition of fine inert material. An example is precipitation of carbon soot on the ore particles. As a result of these successful developments, fluidized beds gained increasing interest in recent years.

The reduction rate in the fluidized bed is determined by the rate of the interfacial reaction, particularly at low temperature. The rate of the interfacial reaction increases with increasing total pressure (see page 46). Increased pressure also results in an increase in the normally low heat capacity of the hydrogen and, hence, in a rapid heating of the ore by the reducing gas.

2.4.4. Limiting Conditions for Smelting Reduction Processes

Smelting reduction processes are usually operated in connection with prereduction of the iron ore in the solid state. Limits of energy consumption and productivity follow from a consideration of the entire two-stage process of pre- and smelting reduction.

Energy Consumption. The energy consumption of smelting reduction processes is composed of two parts. First, the oxygen separated from the reduced iron oxide is bonded to carbon monoxide, which corresponds to a certain amount of carbon as part of the fuel and hence, the energy consumption. This is the chemical part of the energy consumption. Second, energy is expended to satisfy the heat demand of the endothermic reduction reaction, which is the thermal part of the energy consumption. That part can be supplied (see Section 2.2.2) (1) by electrical energy, (2) by combustion of an additional amount of carbon to carbon monoxide, and (3) by post-combustion of CO and H_2 to CO_2 and H_2O.

The energy is almost completely consumed in the smelting reduction stage, whereas prereduction of solid ore with ($CO + H_2$) from the

Table 17. Process data for various procedures of smelting reduction [216]

Characteristic	Heat supply			Heat supply with fossil energy

* Composition: 82.8 % C, 6.2 % H, 8.0 % O, 2.0 % N 1.9 % S.
** Without energy consumption for gas washing.

smelting reduction stage is thermally nearly neutral. Energy consumption values calculated for off-gas temperatures of 1500 °C are shown in Table 17 for the three aformentioned ways of energy supply [216]. Prereduction is assumed to proceed countercurrently. For better comparison heat losses and heat consumption for slag formation and oxygen production are not considered. Taking these amounts in account, the total energy consumption can be estimated to be 20 to 40 % higher. It is further assumed that the conditions of Figure 22 are fulfilled. This yields the optimal operating point of the system.

Operation without Post-combustion. Row 2 in Table 17 shows the values when electrical energy is used for heat supply. Under this condition, carbon serves only for reduction. The degree of prereduction is 47 %, and the reduction gas is almost completely utilized. Operation is practically autothermic. The procedure is applied in the plasma-smelt process.

Rows 3 and 4 show results when additional carbon is combusted to carbon monoxide in the smelting reduction stage to supply the heat demand for reduction. As the optimal gas utilization is ca. 50 %, the fuel consumption is higher than if electrical energy is used. Coal lowers the gas utilization in comparison to pure carbon or coke due to its hydrogen content (row 4).

Operation with Post-combustion. A solution of the problem of limited gas utilization, if carbon or coal is the only heat supplier, is post-combustion of the process gas of smelting reduction (cf. Section 2.2.2). Rows 5 to 8 show results when the process gas is post-combusted. In rows 5 and 6 post-combustion of the process gas amounts to 10 and 20 %, respectively. CO_2 must be washed out from the gas in this case, in order to make it usable for prereduction. If CO_2 is not removed (row 7), the same situation in respect of gas utilization and total energy consumption exists as in processes without post-combustion (compare row 7 with row 4). If post-combustion is increased to 50 % and more (row 8), the smelting reduction process becomes autothermic for the reduction of wustite, and the thermodynamic limit of FeO – Fe gas reduction vanishes (cf. Section 2.2.2). Gas washing is no longer necessary. Gas utilization becomes 83 %, which is almost the same as in the case of reduction with electrical energy.

Productivity. It is known from the blast furnace and from converter processes that productivity is mainly determined by the maximum possible gas throughput. The iron-bath reactor for smelting reduction may be compared in this respect with a steel converter [80]. Application of this fact to smelting reduction vessels together with plant experience yields a specific gas throughput of an iron-bath reactor for smelting reduction operated under atmospheric pressure of 3 – 5 mol m^{-3} s^{-1} [71, 81]. The productivity of a process is generally defined as

$$P = \frac{\text{maximum volume} - \text{specific gas throughput}}{\text{amount of gas/kg fuel} \times \text{fuel consumption}} \qquad (150)$$

A coal consumption of 600 kg coal/t hm (hm = hot metal) = 570 kg coal per tonne Fe for a smelting reduction process [82] then yields with a volume-specific gas throughput of 3 mol m^{-3}

s^{-1} for a 100 t smelter [81] and 0.087 kmol gas per kilogram coal a productivity of 5.2 t Fe m^{-3} d^{-1} [83].

Influence of Pressure and Post-combustion on Productivity. Productivities are influenced by various factors. One of them is *pressure* (cf. Section 2.4.1). Application of pressure enables a higher volume-specific gas throughput and, thus, an increased productivity. The increase is approximately proportional to the square root of the pressure. Another factor is *decrease in fuel consumption*. It reduces the gas production per tonne Fe and, thus, also increases the productivity. For example, an almost autothermic procedure with post-combustion as that in row 8 of Table 17 has a gas throughput which is 0.65 times that of row 3 in the same table without post-combustion. That would increase the productivity according to Equation (150) from 5.2 to 5.2/0.65 = 8.0 t Fe m^{-3} d^{-1}. In this way post-combustion increases the productivity by lowering the coal consumption.

The total productivity P_{tot} of a two-stage pre- and smelting reduction process is composed of the productivities of smelting reduction P_{SR} and of prereduction P_{PR} as follows [83]

$$\frac{1}{P_{\mathrm{tot}}} = \frac{1}{P_{\mathrm{SR}}} + \frac{1}{P_{\mathrm{PR}}} \tag{151}$$

Data of P_{PR} are known for countercurrent shaft furnaces (see Table 18) [83].

Table 18. Productivities of various iron ore direct reduction processes carried out in shaft furnaces with countercurrent flow of gas and ore [83]

Process type	Top pressure, bar	Productivity, t Fe $m^{-3}d^{-1}$
Midrex [84]	1	8.4
Sumitomo [85]	2	9.6
Nippon Steel (pilot plant) [86]	5	13.2

In connection with the mentioned values for smelting reduction of 5.2 and 8.0 t Fe m^{-3} d^{-1} without and with post-combustion, respectively, the data given in Table 19 follow from Equation (151). The value 3.4 t m^{-3} d^{-1} of total productivity for 2 bar pressure and without post-combustion may be compared with the productivity of a blast furnace with increased pressure. It is higher than that of the blast furnace, which amounts to 2.4 t m^{-3} d^{-1} [87]. The difference is mainly due to the fact that in the prereduction stage the space required by the coke in the blast furnace vanishes.

Table 19. Total productivities of two-stage pre- and smelting reduction processes [83]

P_{SR}, t Fe m^{-3} d^{-1}	P_{PR}, t Fe m^{-3} d^{-1}	P, t Fe m^{-3} d^{-1}
5.2	8.4	3.2
5.2	9.6	3.4
5.2	13.2	3.7
8.0	8.4	4.1
8.0	9.6	4.4
8.0	13.2	5.0

Influence of Reactor Size on Productivity. The productivity of an iron-bath reactor depends on the reactor size. With increasing bath height the running length of the gas through the melt and, hence, also the resistance of gas throughput rises. The influence of bath height h on the maximum possible gas throughput $\dot{V}_{\max}$ can approximately be expressed by

$$\dot{V}_{\max} = c_1 \frac{d^2}{h^n} \tag{152}$$

[83], where d is the diameter of the cylindrically assumed vessel, n an unknown exponent and c_1 a proportionality constant. In order to link gas throughput with productivity, it is required to relate the volume flow to the reactor volume $V_{\mathrm{R}} \cong d^2\, h$. For the special case that d/h remains constant, i.e., $d/h = c_2$, it then follows

$$\frac{\dot{V}_{\max}}{V_{\mathrm{R}}} = c_1 \cdot h^{-(1+n)} = \mathrm{const} \cdot V_{\mathrm{R}}^{-\frac{1+n}{3}} \tag{153}$$

According to this equation, the maximum volume-specific gas throughput decreases with growing reactor volume V_{R}, if $n > -1$. The minimum value of n, which is physically possible, is zero. In that case, the resistance to gas throughput does not increase with the bath height. The productivity decreases only because the surface-to-volume ratio becomes smaller at scaling-up. If $n > 0$, the increasing resistance of the bath height to gas throughput acts as an additional factor that decreases the productivity.

2.5. Blast Furnace Process

A schematic drawing of a modern large blast furnace, here for example blast furnace Schwelgern no. 2 of Thyssen Krupp Stahl AG [88], is shown

Figure 52. Profile of a typical blast furnace (Schwelgern no. 2, Thyssen Krupp Stahl AG, total volume 6020 m^3, all dimension in mm) (Original figure kindly supplied by Thyssen Krupp Stahl AG)
a) Bustle pipe; b) Tuyere; c) Tap hole; d) Paul Wurth top; e) Stave; f) Ceramic and chamotte lining; g) Carbon blocks; h) Bottom cooling; i) Graphite; j) Copper stave; k) Cooling boxes

in Figure 52. A blast furnace is principally divided into the following areas: upper and lower shaft, bosh, belly, and hearth (see Fig. 53). The definitions of the furnace volumes, which are important to calculate specific productivity data are as follows:

Working Volume (W.V.) = volume from 1 m below the lower flange of the adjustable throat armor in low position or from 1 m below the lower flange of the open lower bell to the tuyere level; with rotating chute, the distance in question is to be measured from 1 m below

Figure 53. Blast furnace, sectional drawing

the lower flange of the vertically positioned chute to the tuyere level.

Inner Volume (I.V.) = volume of top area as defined for the working volume but to the taphole level (taphole center outside).

The blast furnace operates according to the countercurrent principle (see Fig. 54) [89]. The process principle makes the blast furnace dependent on lumpy materials to maintain a gas-permeable stock column. For this reason, fine grained iron ores are agglomerated, i.e., sintered or pelletized, before being charged into the blast furnace.

The solid materials, such as coke, ores, and fluxes are charged at the furnace top in a defined distribution mode. The burden column in the stack region therefore consists of a layered structure of ores and coke. In addition to its task to generate heat and reducing gas the coke has the important task to build up a supporting pillar for the solid burden column. The supporting pillar must remain permeable for the furnace gas when melting separates the formed iron and the other constituents of the ores, the gangue, from one another. This supporting pillar is called *cohesive zone*. Under the cohesive zone, only coke remains as solid material. It builds up a coke cone known as *dead man* (see Section 2.1.2). The oxygen content of the hot blast blown in through the tuyeres reacts with the carbon of the coke to produce a reducing gas, which ascends in the stack and extracts oxygen from the ores. The gasification of coke carbon with oxygen in front of the tuyeres leads to a high temperature of up to 2200 °C (*flame temperature*). The high temperature area in front of the tuyeres is called *raceway*. Auxiliary reducing agents, such as oil, coal, natural gas, coke oven gas, or plastics wastes, are injected via the tuyeres in order to save coke.

Figure 54. Operation mode of the blast furnace

Components of the slag formed from the gangue are also reduced and dissolved in the hot metal together with carbon coming from the coke. Slag and hot metal are tapped via tapholes in the hearth. Surplus gas is drawn off at the furnace top, cleaned, and used in the iron and steel works for heating purposes.

Figure 55. Reaction zones and profiles of temperatures and reduction degree in the blast furnace [97]
a) Indirect reduction of Fe_2O_3 and Fe_3O_4; b) Indirect reduction of Fe_xO; c) Direct reduction of wustite and Boudouard reaction; d) Melting of iron and slag; e) Reduction of metalloid and FeO in the slag; f) Combustion in the front of the tuyeres; g) Hearth

The bed structure inside the blast furnace was clarified by the study of the commercial size blast furnace [90 – 96]. When the high temperature gas ascends from the raceway through the coke bed in the lower part of the blast furnace (see Fig. 55), it is cooled rapidly to ca. 1500 °C by (1) heat exchange with the coke bed and with molten materials coming down countercurrently, and (2) by the endothermic reaction of the *direct reduction* of molten iron oxide according to the overall reaction

$$C + FeO \rightarrow CO + Fe$$

This overall reaction includes not only the actual reduction of FeO with solid carbon but also the sum of simultaneous reactions for the gaseous reduction of FeO and the Boudouard reaction. When the temperature of the ascending gas and of the burden decreases below 1000 °C, the Boudouard reaction does not proceed any further because of the low coke reactivity. In the *stack region,* the iron oxides are exclusively reduced by carbon monoxide thereby forming carbon dioxide. In addition, the higher iron oxides such as hematite and magnetite are reduced to wustite in the *upper part* of the stack as follows:

$$3\,Fe_2O_3 + CO \rightarrow 2\,Fe_3O_4 + CO_2$$

$$Fe_3O_4 + CO \rightarrow 3\,FeO + CO_2$$

These reactions are often called *indirect reduction* (together with the reduction reaction of $FeO + CO \rightleftharpoons Fe + CO_2$) because the coke present in the stack of a blast furnace does not play a role in the reduction mechanism. The reduction step from hematite to magnetite proceeds quickly and does not play a role in the overall rate law. However, attention has to be paid to this low temperature reaction with respect to reduction disintegration of iron ores, especially of the sinter, which is caused by the lattice rearrangement occurring during the reaction. In the upper part of the stack region, the burden is heated to 800 – 1000 °C. Below the region, considerably wide *thermal* and *chemical reserve zones* appear where the temperature of gas and solids is kept substantially unchanged at 800 – 1000 °C and no reduction of FeO occurs because thermal and chemical equilibrium conditions are almost established between solid phase (Fe – FeO) and gas phase ($CO - CO_2$).

The gas leaves the top of the furnace through four uptakes. The top gas has *chemical energy*

because approximately only half of its carbon monoxide content is utilized during the reduction processes in the upper part of the blast furnace. However, its sensible heat is rather low because of its low temperature of 100 – 230 °C, which depends on the operating conditions. After the top gas is cleaned, ca. 25 – 30 % is usually used to preheat the blast in the hot blast stoves operated on the basis of the regenerative principle, and 15 – 20 % is used to operate turboblowers to introduce the compressed blast to the blast furnace at the required blast pressure. The remainder (50 – 60 %) is used for heating in other sections of the plant. At blast furnaces operated with elevated top pressure, energy is recovered via a top gas recovery turbine (TRT), generating approximately one-third of the electricity needed for blast compression.

Above the tuyere zone heat and mass transfer (for heating up the burden and for the reduction and Boudouard reactions) occur between the ascending gas and the descending burden.

In the *lower part* the *dead man* (see Fig. 56), extending from the hearth bottom to the belly, has a unique and very important function. The dead man is formed by the charge materials' distribution at the top (for example, coke center charging) and by the gasification of the descending coke in the periphery at the tuyere zone. The oxygen injected with the hot blast is almost completely consumed within the raceway. As a result, the coke located in the center of the furnace is not gasified and forms the dead man. The coke forming the dead man is continually renewed.

The hot gas leaving the raceway ascends primarily into the permeable coke bed which constitutes the dead man, and gives its heat to both the coke bed and the molten material dripping down through the dead man. Then the gas ascends through the coke windows in the *cohesive zone.* Here all burden materials except coke soften and are finally melted down. Since the cohesive layers have a high gas-flow resistance, the gas ascends exclusively through the coke windows.

The molten iron and slag produced in that region trickle down through the coke bed to the hearth. During this process, the molten iron which is in contact with coke, absorbs carbon up to the thermodynamic limit.

Figure 56. Schematic of blast furnace (internal situation) a) Stack; b) Cohesive zone; c) Dripping zone; d) Raceway; e) Dead man; f) Hearth

Hot metal and slag accumulate in the *hearth.* The slag floats on top of the metal bath because of its lower density. Therefore, the metal droplets or streams must come down through the slag layer.

The lower hearth is operated batchwise because hot metal and slag were tapped intermittently at intervals of 40 to 50 min. Hot metal and slag are tapped from the furnace through the same taphole. In most cases first the hot metal flows out and the slag appears later. To empty the hearth early tapping of the slag is a prerequisite that prevents rising of the slag level upward in the furnace which could lead to a deterioration in furnace operation.

Large blast furnaces are equipped with up to four tapholes. Here a continuous and overlapping tapping is state of the art. At the blast furnace Schwelgern no. 2 of Thyssen Krupp Stahl AG, for example, tapping technique was converted to continuous operation. At first a twin hole technology was applied which was superseded by the use of three holes [98]. Two tapholes are opened alternately as soon as one hole is empty. The third taphole has its own time characteristics and is opened in each case after a tap-to-tap time of 50 min. The slag is easily separated from the hot metal by a skimmer in a runner system.

The tapped *hot metal* is transported to the steel shop in *refractory-lined ladles* or in a few cases cast into small molds by using a pig-casting machine to produce cold pig iron of ca. 5.0 kg. The slag is either cast directly in a slag pit for solidification, cast in a slag ladle for transportation to the slag pit, or – as common practice today in many blast furnaces – granulated at the blast furnace directly in a granulation device using, for example, high pressure water.

2.5.1. Outline of a Blast Furnace Construction

A large blast furnace has a working volume of up to 5000 m^3, a furnace height of up to 36 m, a height of ca. 130 m including the exhaust pipes for the top gas, and a hearth diameter of ca. 15 m. The furnace must endure high mechanical and thermal loads because of the large weight of the structure and burden column and the high temperature of the hot blast (ca. 1300 °C) and of the burden in the lower part of the furnace (ca. 1350 °C). In addition the gas pressure inside the furnace may be as high as 6.5 bar.

Blast furnaces are today entirely encased in a steel shell (*mantle plate*). They are equipped with a refractory lining inside the mantle plate and with external cooling systems such as cooling boxes and/or stave coolers to cool the lining and the shell.

Blast furnaces are constructed according to two different principles illustrated in Figure 57, which represents the construction principle of the 1960s. In a *free-standing* type of construction (Fig. 57 A), the furnace is self-supporting. The weight of the top-charging gear, the top-gas uptakes and the top of the skip incline (or charging conveyer-belt gallery) is supported by a steel construction surrounding the furnace. In a *shaft-support* ring-type construction (most U.S. blast furnace constructions), the furnace shaft and the entire construction are supported by a mantel ring, i.e., a ring surrounding the furnace and attached at the belly.

Figure 57. Blast furnace support structure [99]
A) Free standing construction; B) U.S. construction
a) Frame; b) Continuous armor; c) Compensation; d) Stack support ring; e) Ring support; f) Support for the top

Figure 58 shows a furnace with its top construction, the hot stoves, and the tap gas cleaning devices, taking blast furnace Schwelgern no. 1 of Thyssen Krupp Stahl as an example. For this furnace, the charge materials are conveyed to the top by a conveyer belt. For older blast furnaces the charge materials are transported to the top by skip cars along a skip incline. Figure 59 gives an example of a modern cast house layout as required for modern blast furnaces, showing full cast house dedusting equipment. The dust sources that need extraction are the taphole, the main trough, the slag skimmer, the hot metal and slag troughs as well as the hot metal and slag transfer points. If the trough system is fully extracted by means of hoods arranged above the troughs, volume flows of up to 1×10^6 m^3

Figure 58. Blast furnace with top construction, hot stoves, and gas cleaning devices (blast furnace Schwelgern no. 1, Thyssen Krupp Stahl AG, original figure kindly supplied by Thyssen Krupp Stahl AG)

Figure 59. Cast house of blast furnace B, Hüttenwerke Krupp Mannesmann

(STP)/h or 4800 m^3 (STP) t hot metal are attained and cleaned in electrostatic precipitators or bag filters.

Large blast furnaces can produce up to ca. 13000 t hot metal per day. These furnaces require up to ca. 20000 t/d of ferrous burden materials and ca. 4550 t/d of coke, if operated with injection of auxiliary reductants and a coke rate of 350 kg/t hot metal. The sinter, which is the most effective ferrous burden material for producing hot metal in the blast furnace, is produced in the sinter plant. The sinter produced is screened and fed directly to the furnace by a belt conveyer, through weighing devices. The sinter may also be stored in intermediate hoppers to provide a buffer whenever production rate fluctuates. The fines created during transportation or storage are separated and recycled to the sinter plant. Coke and fluxes are also added from hoppers. The fines created during coke screening are also recycled to the sinter plant or charged as nut coke (10 – 30 mm) mixed with the sinter to the blast furnace periphery. The separation of the fines is very important to maintain the gas permeability of the burden column (see Section 2.4.1).

Charging. The charging equipment has two functions, particularly for large furnaces: the burden distribution and gas sealing. Appropriate *burden distribution* with respect to both ore : coke ratio and particle diameter over the cross section of the stack at the top of the burden bed is important for optimum gas permeability distribution. The latter provides a better reduction of iron ores in the stack region and higher efficiency of gas utilization. Modern charging equipment possesses a gas-tight sealing to prevent gas from escaping during the charging of the furnace. Gas sealing is nowadays possible even for high top-gas pressure of up to ca. 3.8 bar.

Particular attention should be paid to the materials and structure of the charging equipment because ore and coke are very abrasive. The failure of small and sometimes inaccessible parts leads to production disruptions, which in turn causes downstream installations such as the steel plant and the rolling mills to cease operation.

Furnaces with low Top-Gas Pressure. Older furnaces working with a low top-gas pressure are exclusively equipped with a *dual bell-and-hopper arrangement* for gas sealing. In the U.S. McKee type bell-and-hopper arrangement (Fig. 60 A) presently used, the upper bell with the feed hopper can be rotated, therefore the material fed to the hopper with a conveyer belt or a skip hoist can be distributed uniformly in circumferential direction. As soon as the hopper is filled, the small bell is lowered and the material is charged to the large bell. Then the small bell is closed. Subsequently, the large bell is opened. The material falls into the stack where the stock height is monitored with two stockline indicators.

Furnaces with High Top-Gas Pressure. A dual bell-and hopper arrangement is seldom used for modern blast furnaces working with very high top-gas pressure. Gas-tight sealing is not easy because of the abrasive nature of the dusty top gas which acts as a sand blaster when it passes with high velocity through a narrow leak. The large bell (up to 100 t) is expensive and easily damaged. Hence, charging equipment with up to four bells, with a combination of bells and sealing valves, and with sealing valves have been proposed in only the last 20 years. In the *four bell arrangement* of NKK (formerly Nippon Kokan KK) illustrated in Figure 60 B, the small and the intermediate bells are for gas sealing whereas the large bell is for the distribution of burden. The small bell and the hopper can rotate. By lowering the small bell, the charge falls on the intermediate bell. After closing the small bell, space I is pressurized with cleaned blast furnace gas to a pressure equal to that in the top of the burden bed. The charge is then discharged to the large bell by lowering the intermediate bell. After closing the intermediate bell the excess pressure inside space I is released and the large bell is lowered.

A dual-chamber sealing arrangement by DEMAG is shown in Figure 60 C. Two chambers, each of which can be sealed with two sealing valves, serve as a gas gate preventing the top gas from escaping. The charge enters a movable hopper through two parallel hoppers. The former is equipped with an eccentrically located opening in the bottom. The distribution of the charge over the small bell can be controlled with the movable hopper which influences the burden distribution at the top of the furnace considerably. The most innovative top charging device is the bell-less top of Paul Wurth company (see Fig. 60 D), using a rotating chute. The first Paul

Wurth top closing device was installed at blast furnace Hamborn 4 of Thyssen Stahl AG (today Thyssen Krupp Stahl AG) in January 1972 and developed by Thyssen to operational practice [102]. Up to now, worldwide, 186 blast furnaces have been equipped with this system [103]. This device has at least two hoppers with gas-tight sealing. Therefore, one can be discharging into

the furnace without losing the pressure at the top of the furnace while the other is being loaded. The large bell has been replaced by a chute that can be rotated in order to change its inclination angle. The speed of rotation and the angle of the chute can be independently regulated for almost any desired burden distribution, whereas the flow rate of the materials can be controlled by the valves. In addition, the Paul Wurth top has the advantages of lower height and less weight. For a large blast furnace, the charging device requires only a 30 t crane whereas a large bell and hopper arrangement must be equipped with a 120 t crane. It is also too difficult to obtain a suitable distribution with a bell-and-hopper arrangement. Consequently, most large furnaces employ movable *stockline armors* (see Fig. 61) or rotating chutes for the correct distribution of burden materials.

Lining and Cooling. The lining of a blast furnace is subject to a variety of demands as represented in Figure 62. Accordingly, it is constructed as shown in Figure 65. The throat area and the stack are primarily subject to *mechanical impact* and *friction* from burden materials (Figure 62). The lower stack and the belly are subject to *chemical attack* by alkalis. The alkaline compounds deposited from the gas phase on the cooler part of the stack – particularly on the cooler lining – originate from burden materials which evaporate in the hotter bosh region. They form low melting compounds with the lining components. The lower part of the furnace is subject to *wear* by the hot metal and the slag.

Below the tuyeres the lining consists principally of *carbon bricks.* They are preferred to fireclay bricks because of superior thermal properties. However, they are unstable in the oxidizing atmospheres and dissolve easily in the hot metal. Above the bosh, *silicon carbide* bricks are used in the lower one-third part of the stack. They contribute to effective cooling because of their high thermal conductivity. The upper part of the stack is usually lined with *fireclay* which is sufficiently resistant to abrasion.

The amount of cooling water required for a large blast furnace is ca. 9×10^3 m^3/h. The vaporization loss during a cooling operation is ca. 200 m^3 of fresh water per day. About 18 % of the cooling water is used for the cooling of the bosh and stack, 16 % for tuyere cooling, 49 % for the cooling of the hearth, and the remaining 17 % for cooling of the hot blast valves in the hot blast stoves and of the blast furnace motor units for charging device, dust collector, mud gun, inclined runner, air conditioner, and other equipments.

The stack is equipped with *cooling plates* or *stave coolers* inside the steel mantle down to the belly. The coolers are grouped together. Figure 63 shows the so-called 4th generation cast iron stave of Nippon Steel Corporation as well as the "New Cooling Device" (NCD) of Kawasaki Steel Corporation [106, 107] and the durability of cast iron staves of the first three generations. As can be seen in this figure, the staves of the third generation, that were equipped with additional cooling serpentines in the end of the 1970s, have – after wear of the refractory material – a service life of more than ten years. Since 1985 the fourth generation cast iron staves are in use for the lower shaft and bosh area. These staves have a thickness of only 500 mm including the refractory inserts. The experts of

Figure 63. Development status of Japanese cast iron staves

Figure 64. Cooling systems of blast furnace hearth

Kawasaki Steel Corporation aim at a blast furnace campaign life of up to 30 years. For the second campaign of Chiba No. 6 blast furnace – the first campaign lasted over 20 years and ended in March 1998 after a production of 60×10^6 t hot metal – Kawasaki installed in the lower shaft the NCD cast iron stave, which is supported by horizontal copper boxes and has a thickness of 800 mm including refractory lining. Figure 64 shows schematically the different cooling systems of the hearth walls. The spray cooling (left) requires a periodical cleaning of the shell but enables a complete control of the cooled area. The double jacket cooling (middle) and cast iron stave cooling (right) guarantee a dry shell and are more flexible regarding cooling intensity but are difficult to repair [105].

Copper staves developed by SMS GHH and Thyssen Krupp Stahl AG [108] have come into use at numerous blast furnaces for cooling the lower shaft and belly area. Their installation is also planned for cooling the hearth walls. There is a significant difference between the consistency of heat dispersion of nodular cast iron

Figure 65. Lining and cooling of a modern large blast furnace (Schwelgern no. 2, Thyssen Krupp Stahl AG), hearth diameter 14.9 m, total volume 6020 m^3 (original figure courtesy of Thyssen Krupp Stahl AG)

staves and of copper staves. Due to the low thermal expansion coefficient of the copper staves, these can be longer than cast iron staves. Owing to the formation of stable protective layers by the burden materials, the use of expensive refractory materials to increase the service life of the copper staves can be dispensed with. These protective layers reduce the heat throughput and the wear of the staves to more or less zero [21]. Furthermore, additional furnace volume is gained by this design. With respect to the service life, wear of about 3 mm was measured on the experimental copper staves of the blast furnace Hamborn 9 at Thyssen Krupp Stahl after more than 9 years in operation. The staves were installed in 1979. Worldwide, copper staves are already installed in approximately 35 blast furnaces. The tuyeres are made of copper cast with water cooling. The bottom of the furnace is cooled by air thereby holding the surface temperature of the brick at 200 – 400 °C.

Figure 66. Two sets of tuyere – blowpipe assembly [110] (Courtesy of Thyssen Krupp Stahl AG (A) and Nippon Steel Corp. (B))
a) Tuyere; b) Tuyere cooler; c) Blowpipe with ceramic lining; d) Goose neck; e) Peep site

The cooling system is very important to avoid serious damage to the furnace steel jacket, particularly in the bosh and belly which are subject to a heavy thermal load. Thus the furnace life is extended.

The construction of the refractory lining and the cooling arrangement of furnace Schwelgern no. 2 of Thyssen Krupp Stahl that was blown in 1993 is shown in Figure 65. Particularly noteworthy is the cooling system which consists of copper cooling plates in the wall of the shaft, one row of copper staves in the belly as well as two rows of copper plates, cast iron staves in the bosh, double jacket cooling of the hearth wall, tuyere cooling, and hearth bottom cooling with water. These arrangements suppress thermal stresses in the steel jacket.

The further development of cooling systems depends highly on the development of refractory lining materials with high thermal conductivity. Although high thermal conductivity lining increases the heat losses – thereby requiring a corresponding increase in cooling capacity – it decreases the wear of the lining by allowing a more uniform temperature distribution. The heat loss of the modern large furnaces is less than that experienced in older furnaces because of a smaller surface area : volume ratio. The hot blast pipe and the tuyeres in the new furnaces shown in Figure 66 are also refractory lined because the hot blast temperature is as high as 1350 °C.

Blast. Forty years ago the hot blast temperature was ca. 800 °C. It has been increased up to 1350 °C at present. This has been made possible through the development of high performance hot stoves in the 1960s. Blast temperatures of 1300 to 1350 °C at dome temperatures of 1550 °C were achieved via constructive improvements (hot stoves with external combustion shaft), through heating with rich gas and through the use of silica checker work instead of chamotte checker work. The development of injection technologies was the main prerequisite to use such high blast temperatures because the injectants have a cooling effect on the flame temperature which increases with increasing H_2 content in the injectants. This makes it possible to keep the flame temperatures on a suitable level of 2200 °C, when using hot blast temperatures exceeding 1200 °C. The hot blast temperature could be increased because the gas permeability was increased by elimination of fines and the beneficiation of iron ore which led to lower gangue content, narrow temperature range for

cohesion, and lower reduction disintegration and swelling.

Figure 67. A) Hot blast stove with external combustion chamber [99]
B) A design of checker-building shape for blast temperature up to 1350 °C

The higher blast-temperature increases the production efficiency of the furnace. In addition, the larger part of the blast furnace top gas is utilized for preheating the blast. This results in a decrease in coke rate (coke consumption per tonne of hot metal) because the thermal energy that would otherwise have been lost from the process is returned to the blast furnace in the form of sensible heat. The hot blast stoves for blast furnaces work exclusively on the basis of the regeneration principle that was applied to preheating the blast air for blast furnace operation by E. A. Cowper in 1860. Most blast furnaces are equipped with three or four hot blast stoves. After cleaning, the top gas is used for preheating the blast by combustion in a combustion chamber. The top gas is sometimes enriched with natural or coke oven gas to improve its calorific value. The waste heat of the hot blast stoves can also be used to preheat combustion media. A waste gas heat exchanger, for example, is installed in the main waste gas collector in which waste gas is cooled from a maximum of 300 °C to 123 °C [109]. The heat recovered in this way is conveyed via a thermal oil system to the hot blast stoves and there transferred to the combustion air and gas. The combustion media are heated to around 180 °C. The oil circulation to the heat exchangers of those stoves that are on blast is shut off. The hot gas obtained by combustion is directed from the top to the bottom through a checker column where the thermal energy is stored. After switching to wind, the cold blast is then directed through the column of checkers. Depending on the temperature, the hot blast coming from a hot blast stove is mixed with a certain amount of cold blast or with a lower temperature blast generated from another stove where the temperature has already been decreased.

This mixing is done to regulate the temperature of the hot blast or to keep it constant. A hot blast stove with an *external* combustion chamber to generate high blast temperature is shown in Figure 67. High temperature hot blast stoves with an *internal* combustion chamber are also still in use.

The required size of the hot blast stove is calculated from the following equation:

$$B\Delta \mathrm{T_B C_p\,(B)} = \frac{\mathrm{G\,(LHV)}\,\eta}{100}$$

$$= z\,\varepsilon\, m_{\mathrm{st}} C_p\,(\mathrm{s})\,\Delta \mathrm{T_s n} \qquad (154)$$

where B is the quantity of air [m^3 (STP)/s]; ΔT_{B} the temperature difference between hot and cold blast air (K); C_p (B) the average specific heat of air at standard conditions [J m^{-3} (STP) K^{-1}]; G the quantity of heating gas [m^3 (STP)/s]; LHV the lower heating value of the off-

gas [J/m^3 (STP)]; η the efficiency of the hot blast stove, (%); z the number of hot blast stoves; ε the utilization factor of the checker brick; m_{st} the mass of the checker brick (kg); c_p(s) the average specific heat of the checker brick (J kg^{-1} K^{-1}); ΔT_s the average temperature difference of the checker brick from the beginning to the end of the blast cycle (K); and n the number of cycles per stove and second.

The quantity of air B depends stoichiometrically on the coke rate. When a blast temperature is specified, the output power of the stove required and the value of B can be read from Figure 68 for a specific coke rate which is the independent variable. The thermal efficiency η is ca. 90 %, taking into account the heat loss which includes the heat loss in the bustle pipe. The utilization factor ε of the checker brick takes into account that the center of the brick has a lower temperature than its surface. The value of ε is 0.9 for a blasting period of 0.5 h and an equivalent brick thickness of 30 mm. The temperature variation ΔT_s at the surface of the brick must not exceed 130 K in order to generate high blast temperature.

Figure 68. Output power required for a hot blast stove vs. coke rate with temperature as a parameter [111]

To estimate the mass of the checker brick from Figure 68, the power density is assumed to be 35 kW/t. Then, the required checker mass is found to be 7500 t for a coke consumption of 4000 t/d and a blast temperature of 1350 °C. Figure 67 A shows a checker brick column which is economically attractive because of the smaller required brick quantity, its stability to mechanical and thermal load stability and the resulting uniform flow conditions.

Gas Cleaning. The blast furnace generates 1400 to 1700 m^3 (STP) dry top gas per tonne hot metal, depending on the operation mode. The uncleaned top gas contains up to 30 g dust/m^3 (STP). The dust content must be decreased to below 10 mg/m^3 (STP) due to the works' own specifications in order to use the gas in the gas turbines for the blast, to protect burner equipments of other plants in the iron and steel works where the gas is utilized, and due to environmental regulations. The volume of the top gas to be cleaned for a large blast furnace with a production of over 11000 t hot metal per day amounts to more than 16 $\times 10^6$ m^3 (STP) per day.

Because of the cost associated with gas cleaning installations, it has become commonplace for large blast furnaces to operate the compressors for the blast with electric motors instead of gas turbines. The top gas is used for heating purposes. The exhaust gas from the boiler contains 10 – 50 mg dust per cubic meter (STP). It falls within the legal limit for dust emission. Figure 69 shows a schematic of the initial part of the top-gas cleaning system. At first, a dust catcher reduces the dust content of the top gas from 10 – 30 g/m^3 (STP) to 5 – 10 g/m^3 (STP). The dust content is further lowered to < 5 g/m^3 (STP) by the cyclones. Pressure losses occur in the dust catcher and the group of cyclones as well as in the venturi scrubber. In high-top-pressure blast furnaces, in which higher pressure losses are admissible, the top gas cleaning system is often a combination of dust catcher, cyclones, and venturi or ring slot washer. After cleaning, the pressure of the top gas can be about 2 bar higher than that of the works gas system and this excess pressure can be utilized in a turbine for power generation.

The amount of dust and sludges removed by the gas cleaning system are between 8 and 17 kg/t hot metal depending on the operation

Figure 69. Top gas cleaning system [99]

mode of the furnace. The process water produced by wet cleaning of the top gas is treated in sedimentation tanks. The blow down is often added to the slag granulation water. The excess water from slag granulation is then conveyed to a purification plant.

2.5.2. Metallurgy of the Blast Furnace

The hot metal produced in the blast furnace is saturated with carbon and is in the liquid state. Depending on burden composition and operation technique of the blast furnace, the molten hot metal produced contains varying amounts of other elements such as silicon, manganese, phosphorus and sulfur. The blast furnace produces hot metal, not steel.

A blast furnace is operated under the following three major prerequisites:

1) *Lowest energy consumption,* particularly the lowest coke rate;
2) *High productivity*, i.e., a high production rate per unit volume of the furnace;
3) *Composition* and *temperature* of the liquid hot metal produced must meet the requirements of the steel shop and must be constant.

Mass and Heat Balances. Table 20 shows the simplified mass and heat balances of the reactions that proceed sequentially during the descent of the burden in the blast furnace. All figures in the table are based on 1 mol Fe_2O_3, 1/4 mol $CaCO_3$ as a flux, and k mol of coke as reductant.

Hematite is first reduced via magnetite to wustite by the gas. Because the heat requirement of the reactions are small, the heat content of the gas is sufficient for heating the burden (see Fig. 70). The gas composition prevailing in the upper part of the furnace (below 1000 °C) has the reducing potential for hematite and magnetite as depicted in Figure 71. Only a portion x of the wustite is reduced to iron because of kinetic limitation. The deviation of the gas composition from the Boudouard equilibrium *above* 650 °C is due to the low reactivity of coke. Thus, carbon dioxide is not adequately converted to carbon monoxide. Deviation *below* 650 °C is caused by suppression of the carbon deposition reaction, $2\ CO \rightleftharpoons CO_2 + C$. For coke saving, the former deviation from equilibrium is desirable, however, the latter undesirable.

Figure 70. Schematic profile of temperature and gas composition in the longitudinal direction of the blast furnace

Figure 71. Variation of temperature and gas composition in a typical operation of the blast furnace superimposed on the reduction equilibrium diagram of iron oxide

During descent of the burden, limestone starts to decompose at ca. 700 °C. This reaction requires heat and releases carbon dioxide, therefore the gas is cooled and its carbon dioxide content increases. Consequently, the reduction rate of iron oxide decreases and the value of x in Table 20 decreases. A lower value of x corresponds to a higher coke rate according to the balance shown in Table 20. The wustite that has not yet been indirectly reduced by the gas to iron must be reduced directly with carbon. This reaction requires a great amount of heat. For simplicity it has been assumed in Table 20 that direct reduction of wustite proceeds at 1100 °C. This zone of the furnace is critical for the completion of the entire process. The amount of oxygen which *must* still be removed from the ore in this part of the furnace depends on the degree of reduction achieved in its upper part. Therefore the residual amount of oxygen depends on the reducibility of the ore. On the other hand, the amount of oxygen which *can* be removed from the ore in this zone depends on the enthalpy that is delivered by the gas at 1100 °C. This enthalpy, in turn, depends on the amount of coke that is available for gasification in front of the tuyeres.

If *excess heat* is available, a higher top-gas temperature is found. However, the utilization degree of the gas η_{CO} decreases because the excess heat is supplied by gasification of coke to carbon monoxide. This phenomenon can be controlled by decreasing the coke rate of the burden materials fed at the top of the bed. However, the action will only be effective after 4 – 6 h when the burden charged at new rates comes to the tuyere zone. An immediate effect is obtained if the heat input to the lower part of the furnace is decreased by increasing the moisture content or decreasing the temperature of the blast.

It is more difficult to compensate an *enthalpy shortage* in the lower part of the furnace. An increase in the coke rate is effective only after several hours. It is often not possible to increase the temperature of the blast because the blast temperature is usually at its maximum for economic reasons. The maximum blast temperature is limited by the capacity of the stoves and also by the maximum allowable flame temperature of the blast furnace. A short-term solution to compensate an enthalpy shortage is to inject reductants such as hydrocarbons, natural gas, oil, or pulverized coal together with an oxygen enrichment of the blast.

Upon further descent of the burden, the enthalpy $\Delta H_{E,\,S}$ needed to melt iron and slag must be supplied. For simplicity, they are assumed to melt down at 1300 °C (see item 6 in Table 20).

The various heat sinks are compensated by the equal amount of heat supplied from the gasi-

[a] Heat of reaction not based on reaction temperature.
[b] t_B = Hot blast temperature. t_R = Temperature at which the direct reduction is assumed to proceed.

fication of the coke and from the hot blast as described in items 7 and 8 in Table 20. This requirement almost determines the coke rate for various conditions. This is an approximate calculation because the coke requirement for the reduction of molten wustite, silica, and manganese oxide as well as that for the carbon dissolved in the metal has not been taken into account. To consider the heat and mass balances, the furnace is divided into two parts by a boundary line which is drawn in the thermal and chemical reserve zone. In this zone, the temperature is almost constant (ca. 900 °C) and no reduction of iron ores occurs.

The coke rate is determined by the enthalpy requirement of the lower furnace. The quantity of carbon y (mol of carbon per moles of hematite to be reduced) needed to supply the heat is given by Equation (155) (for symbols see Table 20):

$$y = -\Delta H_{E,S} + \frac{(1-x)\,\Delta H_{CO}}{\Delta H_C + \Delta H_L} \tag{155}$$

k, the total amount of carbon required, is given by (see Table 20):

$$k = y - 2x + 2 \tag{156}$$

The amount of carbon required for direct reduction is:

$$k - y = -2x + 2$$

Substitution of the figures listed in Table 20 gives the carbon rate as a function of the hot blast temperature t_B and the amount of wustite reduced indirectly x, assuming that the direct reduction proceeds primarily at t_R = 1100 °C

$$k = \frac{357}{111 + 0.084(t_B - 1100)} - \left(\frac{2 + 315}{111 + 0.084(t_B - 1100)}\right) x + 2$$

The coke rate Q is then given by:

$$Q = 118k$$

on the basis of a carbon content of the coke of 85 % and on iron content of the hot metal of 93.5 %.

The *fraction of indirect reduction* r_{CO} indicates how much oxygen has been removed from the ore by indirect reduction. Together with the fraction of direct reduction r_C, the sum should be equal to unity:

$$r_{CO} + r_C = 1 \tag{157}$$

For reduction of hematite, the following relation is valid (Table 20, items 2 and 3):

$$r_{CO} = \frac{O_{removed}}{O_{total}} = 1 + \frac{2\,x}{3} \tag{158}$$

On the basis of the *balance* shown in Table 20, it is not possible to assign a value to x (amount of wustite indirectly reduced). The maximum value of x can be determined thermodynamically. If the value of x is given, then r_{CO} is obtained from Equation (158). In fact, the value of x is determined by the rate of the indirect reduction of iron ore and by the reactivity of the coke which, in turn, determines the degree to which the Boudouard reaction proceeds. The value of x can be evaluated from the composition of the top gas if the operational data are available. The gas utilization factor is defined by Equation (159):

$$\eta_{CO} = \frac{\%CO_2}{\%CO_2 + \%CO} \tag{159}$$

Substitution of the values in Table 20 provides the following Equation:

$$\eta_{CO} = \frac{(1+2x)}{2\,(1-x) + y} \tag{160}$$

Since y depends only on the enthalpies and x for a given blast temperature (see Eq. 110), the value of x can be determined if the decomposition of limestone is neglected. In practice, r_{CO} is between 0.45 and 0.65 and the corresponding values of x are between 0.175 and 0.475.

The *amount of air* l required per mole of hematite and the *amount of top gas* generated g_G are obtained from Table 20:

$$l = \frac{5y}{2} \text{ (amount of air)} \tag{161}$$

$$g_G = 3y - 2x + 2 \text{ (amount of top gas)} \tag{162}$$

These equations are approximate expressions and should be improved for more accurate calculations – particularly when the calculated results are to be used for furnace control to keep the composition and temperature of the hot metal constant. For this purpose it is necessary to formulate the heat and mass balances on hydrogen from water vapor and hydrocarbons and on the solutes in the iron (e.g., carbon, silicon, manganese, and phosphorus).

2.5.3. Effective Utilization of Energy

The high thermal efficiency of the blast furnace (Table 21) directly leads to a low coke rate. Heat losses through the wall in this example amount to ca. 4 %. Additionally, 2 – 5 % of thermal energy is lost in the form of top-gas enthalpy. These values decrease with increasing furnace size so that the total loss of thermal energy is <6 %. Compared to the low *thermal energy loss* of the blast furnace, the *chemical energy* of the top gas is rather large and amounts to ca. half of the thermal energy used effectively in the furnace.

Table 21. An example of enthalpy balance for the modern blast furnace (no. 6 BF at Chiba works of Kawasaki Steel Corp.)

[a] TRT: Top-gas pressure recovery turbine.

The thermal energy supplied by the hot blast (Table 21) should be partly subtracted from the total energy required for the blast furnace operation because the blast is primarily heated by the top gas. Even in modern blast furnaces ca. 30 % of the primary energy supplied by coke leaves the process in the form of carbon monoxide and hydrogen in the top gas. A heat loss of 3 – 7 % is caused by *slag enthalpy.* With these

considerations in mind, lowering of the energy requirement can be accomplished as follows:

1) Use the chemical energy of the top gas as efficiently as possible in the process system,
2) Decrease the specific slag volume,
3) Prepare the burden (operation of the stack), i.e., carry out dehydration and decarbonization outside the blast furnace by utilizing inexpensive energy sources.

Additionally, efforts exist to replace metallurgical coke by other inexpensive energy sources because of high cost of coke. Table 22 shows the calculated energy balance of a blast furnace which is fitted well to newer operational results [72]. These calculations were done to assess whether carbon and hydrocarbon carriers are used in the blast furnace as fuel or as chemical raw material. Table 22 indicates that about 70 % of the energy supplied by the coke is converted into energy that is chemically bonded in the hot metal. 14 % equates to the low calorific value of the top gas which is inevitably produced in the blast furnace process and which is used in other parts of the integrated iron and steel works. Only 13 % of the energy converts into measurable heat of the hot metal and the slag. In this case only about 3 % is lost through the heat loss of the furnace walls or through the top gas.

Similar conditions prevail if coke replacement materials are injected via the tuyeres. The utilization ratio of reducing agents and energy used for the blast furnace process thus amounts to 97 %, which is an outstanding value. The carbon and hydrocarbon carriers used in the blast furnace should be classed as "chemical raw materials" and not as "fuels" as their components are mainly involved in the chemical reactions of the iron ore reduction [114].

Blast Furnace Operation and Physical Properties of Burden Materials. The heat required to produce 1 t of hot metal substantially depends on the physical properties of the iron ores. In modern blast furnace operation, processed ores such as sinter and pellets are usually fed to the furnace to conduct stable operation for pursuing higher productivity and lower coke rate. Physical properties which significantly affect the blast furnace operation are reducibility and reduction disintegration. *Higher reducibility* contributes to the increase in indirect reduction

Figure 72. Influence of FeO content in sinter on the reducibility [115] (Courtesy of The Iron and Steel Institute of Japan)

Figure 73. Relation between FeO content in sinter and reduction disintegration degree [116] (Courtesy of The Iron and Steel Institute of Japan)

in the stack region thereby increasing the utilization factor η_{CO} and decreasing the coke rate because of a decrease in direct reduction. *Reduction disintegration* directly affects the gas permeability of the burden column and may cause flow maldistribution which negatively affects the reduction of iron ore and gas utilization. There-

fore, the physical properties of the sinter should be controlled appropriately. A lower FeO content in the sinter enhances the reducibility, however, a higher content improves the reduction disintegration as shown in Figures 72 and 73.

A low gangue content of the burden materials also contributes significantly to the coke savings by decreasing the slag volume.

Chemical Energy of the Top Gas. Burden materials with a high reducibility and a low reduction disintegration provide a low coke rate, but a high gas utilization factor η_{CO}. A better burden preparation allows the use of higher blast temperatures which results in the use of a larger portion of the top gas for heating the blast. These circumstances significantly decrease the waste energy that leaves the blast furnace process in the form of off-gas. Figures 74 and 75 illustrate the average decrease in the coke consumption and the total reductant consumption, respectively, of the blast furnaces operated in Germany and in Japan [21]. They also show the effective replacing of coke by oil and pulverized coal. A productivity increase of a blast furnace is coupled with an increase in gas throughput and a reduction of the specific gas volume. A reduction of the specific gas volume can also be obtained by reducing the consumption of the specific reducing agents.

The productivity increases of the blast furnaces in Germany and in Japan took place simultaneously with the decrease in reductant rate. It is noticeable that in Japan a high capacity level was attained much earlier than in Germany. This is due to the setting up of the Japanese steel industry in the 1960s using large blast furnaces and, at the same time, the latest plant technology. However, the closer the reducing agents consumption gets to the process technology minimum, the flatter the curve becomes. Additional reserves for increasing productivity and decreasing reducing agents consumption could be exploited by changing the structure of the reducing agents in conjunction with the use of higher amounts of oxygen as well as improvements in burden qual-

Figure 74. Development of the average reducing agents consumption and the average productivity of blast furnaces in Germany

Figure 75. Development of the average reducing agents consumption and the average productivity of blast furnaces in Japan

ity. The theoretical limits of the coke rate for a fully oxidized burden is approximately 400 kg/t hot metal, for the use of 60 % prereduced burden approximately 350 kg/t hot metal and for the use of 100 % prereduced burden lower than 250 kg/t hot metal. When 100 % prereduced burden is used, the blast furnace is operated as a melting furnace like a cupola that produces cast iron. In this case, a gas with a very high calorific value is produced because the blast furnace works as an iron and gas producer. Prereduced burden such as hot briquetted iron (HBI) from direct reduction plants is only used in a few blast furnaces in the world in small amounts to increase productivity. Compared to sinter and pellets, HBI generally is an extremely costly burden material for blast furnaces.

In spite of the successful efforts to decrease the coke rate and to use auxiliary reductants since the 1950s, the problem to what limit the coke rate can be lowered is still not solved. Sufficient coke must be present in front of the tuyeres to form a dead man (Section 2.5) through which the gaseous products can ascend. In addition, the coke consumed in the dead man must be replaced. If the quantity of coke required for these portions of the process is not available, then the characteristics of the process change and it can no longer be called a blast furnace process.

Figure 76 gives a schematic illustration of the processes occurring in the raceway in front of the

tuyeres [118]. According to direct observations, coke particles are entrained in the turbulent air flow immediately in front of the tuyere opening and fly on circular trajectories within the raceway.

Figure 76. Movement of coke particles in front of the tuyere and location of gasification zone (raceway)
a) Packed zone; b) Coke fluidizing zone; c) Coke slow moving zone; d) Blast jet

The coke particles are primarily gasified in the raceway. According to the gaseous composition distribution in the raceway shown in Figure 77, coke burns with the gas at first forming carbon dioxide, and then carbon dioxide is reduced to carbon monoxide in an area near the coke-filled bed. A typical gas composition change from the tuyere via the raceway to the packed bed calculated by a two-dimensional model [119] is shown in Figure 78. From this figure the gasification reaction has almost gone to completion in the raceway region, therefore a very small quantity of CO_2 is left for the coke packed bed around the raceway.

Figure 78. Change of gas composition from the tuyere to the packed bed

Moreover, the direct observations indicate that a shower of iron and slag droplets descends in front of the tuyeres, together with coke particles falling through the air flow. In addition, in no other part of the raceway roof was the burden observed to descend. On the basis of these observations it is assumed that the molten iron and slag trickles down in the space between the in-

dividual tuyeres and within the dead man. This phenomenon has been proven by dissection of blast furnaces [90, 120].

Fluid flow studies have shown that the adequate quantity of gas cannot flow through the cohesive layers or through the layers which hold up the molten materials unless a sufficient volume of coke bed (which has a high permeability) is present inside the furnace.

Basic Concept to Improve Blast Furnace Performance. The following technologies or their combinations have been principally approved to decrease the coke rate and to increase the productivity of the blast furnace:

1) Pretreatment of iron ores improves the reducibility and permeability and hence, increases the gas utilization η_{CO}. Examples are *sintering* or *pelletizing* of the ore and *screening* to separate the fines.
2) Injection of *auxiliary reductants* such as hydrocarbons, oil, and pulverized coal replaces coke for heating and reduction purposes.
3) Oxygen enrichment of the blast together with reductant injection decreases the amount of blast; this decreases the amount of top gas per tonne of coke and increases the furnace efficiency.
4) *Increase in the blast temperature* reduces the amount of coke required for heating.

Figure 80. Effect of measures to decrease the coke rate and to increase the productivity of the blast furnace estimated by the Rist diagram [111]
Line 1: normal blast furnace operation (standard); Line 2: improvement in gas permeability and reducibility; Line 3: improvement in indirect reduction (K_3) by injecting reducing gas into the stack

5) *High pressure operation* allows the introduction of a larger amount of blast per unit time.
6) *Reducing gas injection* in the lower part of the stack lowers the amount of coke required for reduction.
7) The use of *partially reduced ore* results in a decrease in the coke rate and an increase in the productivity of the furnace.

The effect of these various technologies on the coke rate and their limits of applicability can be summarized with the aid of the extended Rist diagrams shown in Figures 79, 80 and 82.

Table 23 lists quantitative results obtained from operational data concerning the technologies applied to decrease the coke rate on the basis of the Rist diagram and to increase the productivity.

Curve 1 in Figure 79 represents the conditions in a blast furnace without additional technologies. Heat is liberated during the oxidation of carbon (coke for heating) by the hot blast (E to F). The segment FG represents the reduction of elements dissolved in iron and segment GK corresponds to direct reduction. The indirect reduction is represented by the segment AK. The diagram allows the determination of the amount of carbon required per mole of iron (C/Fe) and the amount of coke (85 % C) required per tonne of hot metal (93.4 % Fe). For this purpose, the operating line 1 is shifted to the line 1 a, which

Table 23. Effect of various parameters on the coke rate of the blast furnace, based on 1 t of hot metal [112, 113]

Parameter	Range	Change	Effect on coke rate kg/t hot metal

goes through the origin. The intersection of 1 a with the abscissa in the upper part of the diagram together with curves I or II gives the carbon consumption (C/Fe) on the ordinates I or II on the left side, while the coke consumption can be read from the ordinate on the right. The lower abscissa (0 – 100 %) is valid for the segment between E and K. It shows the coke consumption for heating (EF), for reduction (GK), and for the reduction of minor constituents in the burden (FG). For the blast furnace operation in accordance with line 1, the coke rate is 550 kg per tonne of hot metal which is equivalent to a C : Fe ratio of 2.3. The consumption ratio is 60 % for heating, 25 % for direct reduction, and 15 % for the reduction of the minor constituents in the burden.

Lines 2 and 3 are theoretical operating lines for obtaining the limits of the coke rate. *Line 2* (no coke used for reduction) is based on the assumption that the reactivity of the coke is so poor that the Boudouard reaction and the direct reduction are suppressed completely. However, it is also assumed that a gaseous composition is reached which corresponds to the reduction equilibrium from wustite to iron (point W). In this case the entire quantity of carbon monoxide required for the reduction must be generated by the gasification of coke. This condition causes the extremely high coke rate (line 2 a) of ca. 1000 kg per tonne of hot metal, a lower gas utilization η_{CO} as well as higher temperatures of top gas and molten iron.

Line 3 is based on the assumption that no coke is required for heating and that the total heat required is supplied by a hot inert gas. In that case the coke rate would be ca. 200 kg per tonne of hot metal while the gas utilization would be 80 %.

Line 2 in Figure 80 shows the decrease of the coke rate caused by the improvement of gas permeability and reducibility compared with the standard case (line 1). Line 2 gives an improvement of 5 % in gas utilization thereby more closely approaching the equilibrium point W in the wustite field. In addition, the degree of direct reduction (K_2) decreases, which leads to a coke saving of 30 kg per tonne of hot metal (tHM). The reducibility of various burdens are shown in Figure 81, which were measured according to Japanese industrial standard.

It is evident from Figure 80 that improvement in the physical properties of burdens does not result in a large decrease in the coke rate but

can probably contribute much to the stable operation of the blast furnace. A lower coke rate (i.e., a lower slope of the operating line in Fig. 80) could only be achieved if it were possible to increase the degree of direct reduction together with the gas utilization. This method would lead to an increase in the heat requirement that must be supplied by a hotter blast if coke is to be saved. However, the hot blast temperatures have already reached their technological limit.

Figure 81. Influence of basicity and pellet diameter on reduction degree [122] (Courtesy of The Iron and Steel Institute of Japan)
—□— 1200 °C; —•— 1250 °C; —○— 1300 °C; —×— 1350 °C

Reductants injection through the tuyeres (e.g., pulverized coal or hydrocarbons) can supply a part of the heat requirement. Line 2 in Figure 82 is an example of an oil injection rate of 60 kg/t hot metal and a coke rate of 390 kg/t hot metal (gas utilization ca. 45 %, indirect reduction ca. 75 %). At very high injection rates, the blast is enriched with oxygen or oxygen is injected separately to increase gasification efficiency of the injected reductants. The best figure achieved up to now using oil was an oil injection rate of 155 kg/t hot metal at a coke rate of 283 kg/t hot metal (total reductant rate 438 kg/t hot metal) at blast furnace A of Hüttenwerke Krupp Mannesmann [123], (Fig. 83). A replacement ratio of coke by oil of more than 1.1 was achieved. Figure 84 shows the replacement of coke by injected coal at three European blast furnaces using different coal grades [124]. The total reductant rate achieved at coal rates of up to 200 kg/t hot metal was in the range of 480 to 500 kg/t hot metal.

The highest coal injection rate at a large blast furnace producing basic hot metal was 266 kg/t hot metal achieved at Fukuyama no. 3 blast furnace of NKK Corporation in June 1998 at a coke rate of 289 kg/t hot metal (total reductant rate 555 kg/t hot metal) [125].

In Figure 82 there is a slight break in the line at K_2 which indicates that the quantity of reducing gas is larger as a result of the oil addition than in the case of carbon gasification alone.

Auxiliary injectants can replace coke only up to a certain limit. In the raceway the hydrocarbons are only gasfied to carbon monoxide and hydrogen, liberating less heat than coke per equal quantity of oxygen.

Natural gas

$$CH_4 + (1/2)\,O_2 \rightarrow CO + 2\,H_2 \quad \Delta H_{298} = -36\,\mathrm{kJ/mol} \tag{163}$$

Oil

$$-CH_2- + (1/2)\,O_2 \rightarrow CO + H_2 \quad \Delta H_{298} = -90\,\mathrm{kJ/mol} \tag{164}$$

Coke

$$C + (1/2)\,O_2 \rightarrow CO \quad \Delta H_{298} = -111\,\mathrm{kJ/mol} \tag{165}$$

The higher H_2 content of auxiliary injectants compared to coke leads to a lowering of the flame temperature as hydrogen supplies gas, but contributes no energy to the heating. The cooling effect is therefore lowest for coal and highest for gas (Fig. 85) [126]. An undue lowering of the flame temperature and an incomplete gasification of the auxiliary reductants have a negative effect on the operation of the blast furnace, on

Figure 82. Effect of measures to decrease the coke ratio and to increase the productivity of the blast furnace estimated by the Rist diagram [111]
Line 1: blast furnace operation (standard); Line 2; decrease in the coke ratio through injection of inexpensive energy (best values achieved with Japanese furnaces); Line 3: operation with prereduced ore

total reductant rate of the blast furnace, and consequently on the replacement ratio of coke by injection materials. Thus a given quantity of heating coke can only be replaced by a larger quantity of hydrocarbons if the same amount of heat has to be generated. In other words, the replacement ratio, defined by the ratio hydrocarbons : coke is > 1. However, twice to three times the amount of reducing gas including hydrogen is produced per mole of combustion air (see Eqs. 118 and 119) compared to the combustion of coke (see Eq. 120).

Figure 83. Ratio of coke to oil consumption in Hüttenwerke Krupp Mannesmann blast furnaces A and B

Figure 84. Achieved coke : coal replacement ratios

Figure 85. Change in flame temperature through injection of auxiliary fuels

The addition of hydrocarbons increases the degree of indirect reduction because the reduction rate of hydrogen is higher than that of carbon monoxide. Thus, the degree of direct reduction and its enthalpy requirement decrease. Consequently, the overall effect of hydrocarbon injection on the replacement ratio increases, thereby giving an overall hydrocarbon : coke replacement ratio <1. The enthalpy deficiency which suppresses further increase of indirect reduction becomes increasingly noticeable whenever more coke is replaced by increasingly larger amounts of hydrocarbons. The advantage of the lower reductant cost therefore becomes gradually less. However, a more serious problem is the decrease in the furnace productivity. This must be counteracted by process measures such as reducing the amount of steam, increasing the blast temperature and enrichment of the blast with oxygen or injection of oxygen separately to guarantee a flame temperature of approximately 2200 °C even at very high injection rates.

Figure 86. Injection lances at the Schwelgern blast furnace no. 1 of Thyssen Krupp Stahl AG

Figure 86 shows two lance designs which are in use for injection [127]. Double lances, i.e., two single lances mounted symmetrically, cause the oil or coal jets, which are supplied by the lances, to meet violently and therefore also lead to an improved mixing with the oxygen content of the blast. In coaxial lances, coal is injected through the inner and oxygen through the outer tube. An increase in the amount of oxygen added to improve the oxygen to carbon ratio may be achieved by enlarging the ring slot. A comparative evaluation of single, double and coaxial lances was carried out by temperature measurements and analyses of gas in the tuyere at Thyssen Krupp Stahl AG blast furnace Schwelgern no. 1 (Fig. 87). This evaluation showed that a markedly improved gasification behavior of

Figure 87. Distribution of temperature and composition of gas in the tuyeres of blast furnace Schwelgern no. 1, depending on lance design

the coal is observed when coaxial lances are used. In principle, coaxial lances conform to parallel flow burners, with the disadvantage of an incomplete mixing of the gasification media and large gasification lengths. For this reason an optimized lance design must be used so that the impulse of the oxygen and/or pulverized coal is deliberately utilized. Consequently the mixing of the gasification media is improved, the ignition time is reduced and the gasification increased.

The cost advantage of injecting reductants should take into account that using oil may result in an increase of sulfur input and using coal may result in an increase of chlorine and alkali input into the blast furnace, depending on the grade of purity of the injected reductant. Higher sulfur inputs are associated with higher desulfurization costs, higher alkali inputs are associated with blast furnace disturbances and higher chlorine inputs can damage the wet gas cleaning system. Pulverized coal is more difficult to inject into the blast furnace than oil because it is in the solid not in the fluid state and it contains ash. However, oil or natural gas injection is also conducted depending on local energy conditions all over the world.

Line 3 in Figure 80 shows a break which represents the operation of *injecting a reducing gas* into the stack to promote indirect reduction. This leads to the heating and reducing coke requirement of 390 kg/t (line 3 a). However, inherent to the low coke rate is a low gas utilization η_{CO} of only 30 %. The break in line 3 at K_3 is the result of an increase in the quantity of the gas at the point of injection. This technology has not been accepted for widespread application because of the poor gas utilization and the large amount of top gas. However, the reducing gas injection in the stack region is an important technology for the operation of the blast furnace with pure oxygen [128].

Line 3 in Figure 82 represents a blast furnace operation using *prereduced* ore with a metallization degree of 50 %. This procedure leads to a decrease in the coke rate to 310 kg/t. In this case, gas utilization is only ca. 30 %. Therefore, such an operation is only recommended when the blast furnace capacity is insufficient to satisfy a sudden increase in hot metal demand. The

Figure 88. Phase diagram of the system CaO – Al_2O_3 – SiO_2 [129]

productivity of the blast furnace increases significantly by using prereduced material although it is more expensive.

Slag Practices. The slag must meet the following requirements:

1) It should absorb all unreduced non-volatile components of the burden and remove them from the blast furnace.
2) It should be a liquid of low viscosity.
3) It should be able to absorb the sulfur primarily contained in the reductants and it should contain as little iron oxide as possible to increase the yield of hot metal.
4) The slag volume should be as low as possible without impairing the desulfurization.
5) The temperature range where the burden components become cohesive should be narrow to ensure better permeability of the burden column.
6) Finally, the slag should be converted to salable material.

These requirements are in part complementary and in part mutually exclusive. It is therefore necessary to state priorities.

About 95 % of the slag consists of SiO_2, CaO, MgO, and Al_2O_3. The requirement of *low viscosity* can be met by a variety of components in this quaternary system. Ignoring the presence of MgO, the phase diagram of the ternary system CaO – Al_2O_3– SiO_2 illustrated in Figure 88 shows a low melting temperature region which is parallel to the CaO – SiO_2 binary for low Al_2O_3 content. This region extends from high SiO_2 content to the saturation isotherm for 2 CaO · SiO_2 and then for essentially constant CaO content toward high Al_2O_3 content. The MgO content of the slag does not substantially affect the relative position of the low melting temperature region and only affects the absolute values of the melting temperatures. The compositions of blast furnace slags as encountered under various operating conditions are shown in Figure 89.

As shown in Section 2.2.2, the desulfurization of the hot metal increases with slag basicity, i.e., with increasing CaO and/or MgO content. *Region 1* in Figure 89 can therefore be used only for processing low sulfur burden (e.g., in Brazil where very low sulfur content charcoal is often used as reductant). Because the gangue constituents usually form a low basicity slag, region 1 largely represents the slag composition without addition of fluxes. The furnace can be operated at a relatively low temperature because

Figure 89. Composition of typical blast furnace slags on the CaO – Al_2O_3 – SiO_2 phase diagram (see Figure 88) [111] (for explanation of regions 1, 2, and 3 see text)

of the low melting points. *Region 2* is reached for low iron content burden with *acid gangue* constituents. This mode of operation prevails, for example, in Salzgitter and requires extensive desulfurization of the hot metal outside of the blast furnace. The attainment of a basicity that would result in adequate desulfurization within the furnace would require a large lime addition which leads to a high slag volume and consequently to higher coke rate. *Region 3* represents the worldwide preferred slag compositions for *large blast furnaces.* In this case, depending on the alumina content, dolomite must be added to satisfy the required MgO contents (see Table 24).

Table 24. Optimum composition of blast furnace slag in % [129]

Al_2O_3	CaO	MgO	SiO_2
5	43	16	36
10	44	14	32
15	44	12.5	28.5
20	45	11	24
25	48	8	19
30	56	5	9
35	54	4	7

Slags with higher basicities *B*, as shown in Table 24, would favor *optimum softening conditions.* The softening and melting range of the gangue constituents is ca. 80 – 130 °C for $B = 0.5$ and ca. 20 – 50 °C for $B = 2.0$. Because of the higher melting temperature of the highly basic slag and of the extra energy required due to the larger quantity of flux addition, the slag basicity is maintained at ca. 1.2.

2.5.4. Blast Furnace Productivity Criteria

The production rate *P* (t/d) of a blast furnace has been linked in various ways with the design data of the blast furnace and with metallurgical properties of the burden to give the specific furnace productivity. To date, no consensus has been reached to define a parameter which characterizes the furnace size and can be used in the calculation of the productivity. The characteristic parameters proposed up to now are (1) the hearth diameter, (2) the hearth bustle area that determines the depth of penetration of the blast in front of the tuyeres, (3) the square of the hearth diameter, (4) the hearth area, and (5) the working volume of the furnace. In Germany the working

volume is mostly used as a characteristic parameter for the furnace size, whereas in Japan the inner volume of the furnace is often used.

To compare various furnaces, the *coke consumption* with respect to the hearth diameter is often used. The coke consumption is a criterion (typical parameter) to express the productivity in the furnace which is operated in a given mode. The amount of coke consumed in the furnace is determined stoichiometrically by the constant blast volume blown. If the quantity of blast exceeds the limit, unfavorable phenomena such as hanging of the burden or variations in hot metal composition occur. The following relations have been proposed between hearth diameter and coke consumption:

$$\begin{aligned} D &= \sqrt{4Q/\pi R} \\ Q &= 30.763\times1.829\,(D-1.829-2L_{\mathrm{p}}) \\ Q &= \gamma D^2 \\ \log Q &= 2.59\times\log D+0.73 \\ Q &= 9.06D^{2.22} \end{aligned} \tag{166}$$

where γ is the productivity factor, D is the hearth diameter and R a constant. The production of hot metal P is related to coke consumption per day Q (t coke per day) by the coke rate K (t of coke consumed for producing 1 t of hot metal) and is indirectly evaluated from the quantity of blast blown or the coke consumed:

$$P = Q/K \tag{167}$$

Blast furnaces which are well operated have a specific hot metal production rate $p = P/A$ of 65 t m^{-2} d^{-1} at a coke rate of 470 kg/t HM, a slag volume of 300 kg/t HM, a superficial gas velocity at the top of 3 m/s and a blast temperature of 1100 °C. In Japan specific production rates of 80 t m^{-2} d^{-1} together with slag volume of 180 kg/t HM have been achieved. Productivities based on the hearth area should be interpreted carefully, because the hearth diameter increases during the course of a furnace campaign by the wear of the lining. Therefore, the productivity should be evaluated by using the actual hearth area.

In Figure 90 the coke consumption Q is shown as a function of the hearth diameter for a productivity factor γ between 10 and 25. The daily production rate of some blast furnaces, as a function of the hearth diameter is shown in Figure 91. Curves for the specific hot metal productivity p are also shown for comparison. In practice it has been observed that the specific iron productivity does not increase proportionally for extremely high coke rates because for hard driven furnaces the coke rate K in Equation (167) increases with decreasing gas utilization.

Figure 90. Change of coke consumption with the hearth diameter D and productivity factor γ [131]

Formulae for the *calculation of the productivity* based on empirical observation of operating furnaces have been derived with the aid of regression analysis [132]. These formulae are used to compare various furnaces or used for the design of new furnaces. A regression formula on productivity is given for the blast furnace which produces hot metal for steelmaking (Eq. 168):

$$P = A \frac{\left[\begin{array}{c} 924\,[1 + 4.5\,(O_2 - 2.20)/ \\ 100 + \{l + (m/100)\,(P_t - n)/100\}] \end{array}\right]}{\left[\begin{array}{c} 489 - 0.10\,(t_b - 1132) + 10\,(\mathrm{Ash} - 10.8) \\ + 0.2\,(\mathrm{SV} - 304) - 0.9\,[(\mathrm{SR} - \mathrm{SFPe}) \\ - 71.7] - 0.5\,(\mathrm{OPe} - 9.1) \end{array}\right]}$$

where P is the productivity (t d^{-1} m^{-3}); A a constant (0.85 – 1.15); O_2 the oxygen enrichment of the blast (%); P_t the top-gas pressure (gf/cm^2 = gram force per square centimeter = 98.0665 Pa); l, m, n are constants given in Table 25, t the blast temperature (°C); Ash the ash content in coke (%); SV the slag volume, (kg/t hot metal); SR the sinter ratio (%); SFPe the self fluxing pellet ratio (%), OPe the acid pellet ratio (%).

Figure 91. Relationship between hot metal production rate and the hearth diameter. The curves are for different specific hot metal production rates [132]
a) 50 tm^{-3} d^{-1}; b) 68 tm^{-3} d^{-1}; c) 85 tm^{-3} d^{-1}

The disadvantage of this formula is that it is entirely empirical. It does not predict productivity increases with technological improvements. Important operational data for some large blast furnaces are summarized in Table 26.

2.5.5. Use of Blast Furnace Products

Hot metal, slag and top gas are the products of the blast furnace.

Hot Metal. Most of the hot metal is processed to *steel* by means of the LD (Linz Donawitz) oxygen top-blowing processes. The hot metal used for the LD steelmaking process is known as *basic* hot metal. It is characterized by low phosphorus and low sulfur contents. *High phosphorus* hot metal (Thomas iron) can also be refined to steel by means of the oxygen steelmaking (LD/AC) process. Other types of hot metal are further processed in foundries to *cast iron* or are used as alloys in the steel shop or in the foundry because of their high alloy content (e.g., manganese, silicon). The composition of the common types of hot metal are listed in Table 27. The Bessemer (Thomas) and open hearth processes have been replaced by the oxygen top-blowing processes.

Slags. Depending on the conditions during solidification, the slags produced by the blast furnace are further processed to:

1) Air-cooled slag (solidification in slag pots or pouring pads),
2) Granulated slag (spraying of the liquid slag with water),
3) Pumice slag (foaming with water), or
4) Slag wool (blowing of the liquid slag with air or steam)

Granulated slag can be in the form of pebbles or can have a porous structure depending on the granulation process. The different structure affects the hydraulic-bonding properties, the grindability, and the strength. Granulated slag is used as a material for making blast furnace cement by mixing it with Portland cement after pulverization.

Pumice slag is used in porous form as an insulation and filler material in heavy concrete and as a replacement for other bulk additions.

Air-cooled slag is either ground, such as granulated slag, or crushed and screened to be used as ballast, aggregate, or for road construction.

Slag wool is used in the form of pads for thermal insulation.

Granulated slag for cement	3.46	46.38
Granulated slag for other uses	0.27	3.62
In-plant use	0.11	1.47
Intermediate storage	0.14	1.89
Total	7.46	100.0

In 1997 the blast furnace slag produced in Germany amounted to 7.46×10^6 t [136]. Blast furnace slags were mainly used as mineral material mixtures for road construction (ca. 44 %) and as granulated blast furnace slag – which has excellent hydraulic properties – for the production of blast furnace slag cement (ca. 46 %) (see Table 29). If the granulated blast furnace slag replaces lime, clay, or marl in the cement industry this results in a decrease in energy consumption in cement production and in a decrease in CO_2 emissions.

Top Gas. The top gas consists mainly of N_2, CO_2, CO, and H_2. The utilization degree of the top gas is usually ca. 50 % therefore it is a lean gas whose calorific value is between 2850 and 3560 kJ/m^3 (STP). This value is very low compared to those of coke oven gas and LD gas. Almost all the top gas is used in the iron and steel plant itself which has been extensively discussed (see Figs. 7 and 70).

2.5.6. Process Control

Fourty years ago, the blast furnace process was operated completely by manual control. Relatively few measuring devices were available for process monitoring purposes. Since the 1950s the productivity of a typical furnace has increased by ca. 20 times. This improvement in operation increased the importance of the process control. Modern blast furnaces are therefore equipped with a sophisticated system of measuring and controlling devices, and are directly linked to the process computer (Fig. 92). The latter is often incorporated into the total control system of the whole plant via a larger business computer.

The computer control of the blast furnace process for the optimization of the quality and costs started ca. twenty years ago. Research in this area is still being carried out. Much information can be obtained about the process by measuring the in- and outflows of mass and energy and also about many phenomena taking place inside the furnace. However, the basic problem is to convert these information into control variables to serve the control circuit. The algorithm to evaluate the control variables from the measured values are based on various mathematical models.

Static and Dynamic Models Based on Statistics. In these models the blast furnace is considered to be a black box. The effect of certain deliberate changes in the input variables (e.g., coke addition, pulverized coal injection, moisture content of the blast, back pressure at the top) on productivity, hot metal composition, top gas utilization, etc. is evaluated. With the aid of statistical models, this leads to regression expressions containing the desired algorithms for the determination of the control variables. These statistical blast furnace models that have already been applied successfully do not, in principle, require any knowledge concerning the phenomena occurring inside the blast furnace. An example of such a regression expression is the productivity formula (see Eq. 168) which should only be used for control purposes based on the values of a particular furnace and not based on values collected from various furnace operations. Although it is relatively simple to derive such an expression representing a blast furnace model from operational data, its application is limited.

Figure 92. A control system of blast furnace developed by Kawasaki Steel Corp. [137] (Courtesy of The Iron and Steel Institute of Japan)

If such a model is applied to new operating conditions, then its predictions deviate from reality, the more the new operating conditions deviate from those described by the statistical data. Optimization of the operating conditions becomes stringently conservative when applying statistical models.

Static models based on statistics allow predictions concerning the steady state of the furnace only. *Dynamic models* based on statistics allow predictions concerning the behavior during a transient when passing from one steady state condition to another.

Models Based on Overall Balances. Models derived by taking overall balances represent the internal phenomena of the blast furnace on the basis of two-stage heat and mass balances. The procedure is principally similar to that described in Section 2.5.2 in which the application of the Rist diagram and the heat and mass transfer phenomena (Table 20) were discussed. However, the models are more exact and detailed. A disadvantage of these blast furnace models is that they are unable to predict time-dependent phenomena in the furnace, although data concerning phenomena occurring in the blast furnace are evaluated. For the evaluation of the control variables it is therefore necessary to make assumptions concerning the *thermal equilibrium* between gas and solids in the thermal reserve zone and the *chemical equilibrium* between gaseous components (CO and CO_2) and solid component (iron and wustite), in the chemical reserve zone. The assumption corresponds to point W in the Rist diagram.

In the overall balance model, a direct relationship exists between input and output variables. This is a definite difference to the statistical model. The overall balance model has only one apparent degree of freedom which is the degree of indirect reduction. The existence of this

apparent degree of freedom is caused by a lack of knowledge and will disappear when the internal phenomena of the blast furnace can be measured exactly and incorporated in the model. Under the fixed technological boundary condition the function of the blast furnace is *determined* by these phenomena in combination with certain pretreatment of ore and coke as well as a given hot metal composition.

Kinetic-Dynamic Model. The kinetic-dynamic model in its most extensive form is based on knowledge of all phenomena that constitute the entire blast furnace process. The phenomena include thermodynamic equilibrium and the kinetic relationships that govern the momentum, heat and mass transfer. The model is also based on the knowledge of the behavior of burden materials (e.g., size distribution at the top of the furnace, descending movement, softening and melting), coke gasification, and gas permeability. The model can simulate the behavior of a blast furnace for any given situation with a large computer. All the data required for the model can be determined in the laboratory and essentially need not be corrected with data based on actual operating conditions. The model thus constructed has proved to be advantageous for the study of new processing conditions and the predictions of the operating results without performing costly experiments with the blast furnace. Its disadvantage is the high expenditure required to gain complete information on all the important phenomena occurring in the furnace. For routine blast furnace control, the model must be simplified to reduce computer loads.

The most important kinetic phenomena for constructing the mathematical model by taking differential balances around a control volume are the chemical reactions (e.g., reduction of iron oxide, coke gasification, water – gas shift reaction, and reduction of silica). The reduction rate of *iron oxide* by carbon monoxide or hydrogen can be expressed in terms of the three-interface unreacted-core shrinking model which is represented in Figure 93. Rate and equilibrium constants needed for the rate equation are given in reference [138]. For *silica reduction,* a mechanism via the intermediate formation of SiO gas has been proposed [139]. A rate equation has been derived for the transfer of silicon from the SiO gas to the hot metal in accordance with the mechanism as described by Equation (169).

$$\frac{\mathrm{d}\,[\%\mathrm{Si}]}{\mathrm{d}t} = k_{\mathrm{c}}\,(A/M)\,P_{\mathrm{SiO}} \tag{169}$$

where k_{c} designates the reaction rate constant, A/M the specific area and P_{SiO} the partial pressure of SiO.

Figure 93. Three-interface unreacted core model [138] (Courtesy of The Iron and Steel Institute of Japan)
De_i = intraparticle diffusivity in i-th phase, k_{ci} = rate constant of i-th chemical reaction; k_{F} = mass transfer coefficient through gas film; r = radial coordinate; Y = molar fraction of gas

This mechanism has been found to give excellent simulation results when it is incorporated into the mathematical model.

The *heat transfer* between the different phases in a packed bed is usually expressed in the form of convective heat transfer. The estimation of the heat transfer coefficient is mainly based on the Ranz Equation [140]:

$$N\,u = 2.0 + 0.6(9\,Re_{\mathrm{P}})^{1/2}(Pr)^{1/3} \tag{170}$$

where *Nu, Re_{p}*, and *Pr* designate Nusselt, particle Reynolds, and Prandtl numbers.

Figure 94. Longitudinal distributions of process variables in blast furnace (A) for the case of high-pressure operations [141] (Courtesy of The Iron and Steel Institute of Japan)
t_g, t_s= temperatures of gas and solid; f_s= fractional reduction of iron oxide; f_1= fractional decomposition of limestone; u = superficial gas velocity; p = gas pressure; p_0= top gas pressure; x, y = molar fraction of CO and CO_2; F = volume flow rate of gas; ϱ = gas density; ϱ_b= bulk density of burden bed

However, this equation sometimes gives an inappropriate value. The rate of heat exchange in a packed bed is currently being studied. *Flow maldistribution* of gas in a packed bed can be estimated by using the Ergun equation, a *potential flow mechanism* is often applied to the solid flow [141].

On the basis of the principal concepts mentioned above, *one-dimensional* [142], or *two-dimensional* [141, 143, 144] mathematical models were derived. On the other hand, dynamic changes in the internal situation of a blast furnace were also simulated by an *unsteady-state* mathematical model [145, 146].

Even if a supercomputer is available for the simulation computation of a whole blast furnace, it is still quite difficult to obtain detailed results which include all the phenomena occurring in a blast furnace. Mathematical models presenting some specified phenomena in a blast furnace are effective when detailed information is requested. Such models are developed for analyzing burden distribution at the top of a blast furnace [147], gas flow and heat transfer in the cohesive zone [148], raceway phenomena [119], fluid flow in the hearth [149] and so on.

Some examples of the simulation results are shown in Figures 94, 95 and 96. Figure 94 depicts a one-dimensional distribution of process variables such as temperature, pressure, concentration, and fractional reduction for two different top-gas pressure.

Temperature and gas-concentration distributions reveal the existence of thermal and chemical inactive zones and characteristic distribution of CO concentration which shows maximum value at the position where the CO_2 concentration is zero. The simulation results agree

a) Liquid; b) Fusion zone

well with the principal behaviors of the process variables previously shown in Figures 55 and 70.

Figure 95 shows the streamline of gas, as well as the radial distribution of pressure, temperature and reduction degree, which show a considerable nonuniformity. One of the important problems is how to control or utilize the nonuniformity to improve productivity.

Figure 96 shows computed radial profiles of pressure, gas velocity, and temperatures of gas and solids. In this computation, the layer-by-layer structure of the packed beds and the radial particle size distribution were considered, which markedly affect the gas permeability and then gas flow and temperature distributions.

Complete measurement of the internal state of a blast furnace is very difficult because of its huge size. Simulation technology in combination with operating and some measured data is very important to understand the behavior of the blast furnace.

Application of the Models. The purpose of the blast furnace control during continuous operation is the increase in productivity by stabilizing the furnace operation and the production of high quality pig iron of appropriate temperature and composition. The control variables are (1) ore : coke ratio and burden distribution at the top of the furnace, (2) flow rate and temperature of blast, water vapor addition, and oxygen injection, pulverized coal, oil and fine ore injection.

Originally, attention was paid to the *thermal condition* in the *lower part* of the blast furnace for the stable operation. The so-called *Wu model* was proposed by the Institute de Recherches Sidérurgiques (IRSID) in France. In the model, the heat input into the lower part of the furnace is calculated from blast volume and composition, tuyere injection, and the off-gas analysis. The amount of heat *Wu* is that required for the melting of iron and slag, the reduction of the alloying elements, and compensation for heat loss. The value of *Wu* can be calculated by subtracting the heat consumed by direct reduction of the iron oxides from the total heat supplied to the lower part of the furnace. By maintaining *Wu* at a constant set value, pig iron of a constant composition can be produced.

Figure 97. Heat balance for calculating value of E_c-heat required for the reduction of silicon and for the overheating of iron and slag [150] (Courtesy of the Institution of Mining and Metallurgy)

At the Centre du Recherches Métallurgiques (CRM) in Belgium, a somewhat different model of the same basic type was developed for automatic regulation of the thermal condition of the furnace. In this model, the heat input per tonne of hot metal into the high-temperature zone of the furnace was calculated from the temperature and composition of the top gas, the blast volume, blast temperature, and blast composition. The value obtained is called the heat requirement. The term E_c was defined as the difference between the actual (B_r) and the standard heat requirements (B_s). The latter quantity represents the amount of heat needed to produce a pig iron at 1300 °C containing 0 % Si.

Figure 98. Schematic diagram of a dynamic simulation model of blast furnace [146] (Courtesy of The Iron and Steel Institute of Japan)

The value of E_c corresponds to the heat required for silica reduction and for overheating slag and metal. The heat balance to calculate E_c is shown in Figure 97.

A *one-dimensional dynamic model* was applied to the *unsteady-state* blast furnace operation such as the shut down, the blow-in, and the blow-out together with a *two-dimensional gas flow* model. A schematic diagram is shown in Figure 98. Figure 99 shows the simulation results for the blow-in operation of the blast furnace according to the scheduled increase in blast volume and temperature as shown in Figure 100. The initial condition given to the mathematical model was obtained from the actual filling condition of coke and burden before the start of the blow-in. The results confirm the effectiveness of the model application to the planning of the blow-in operation of the blast furnace. Another successful example for the application of a dynamic model to the actual operation has been reported for the blow-out of the blast furnace. The content of the blast furnace was blown out with the decrease of stock level from the top to the upper bosh under the schedule predicted by the mathematical model. Actual changes of the operation conditions are shown in Figure 101 in comparison with the scheduled ones. The actual results are in reasonable agreement with the schedule (see Table 30). Some improvements to the mathematical model are necessary for obtaining a satisfactory agreement. However, principally such a kinetic-dynamic model is found to be effective not only for steady-state but also for unsteady-state operations.

Figure 101. Results of the empty blow-out operation of the Kokura no. 2 blast furnace [151] (Courtesy of The Iron and Steel Institute of Japan)

The most precise mathematical model of a blast furnace to date is the *two-dimensional steady-state* kinetic model developed by Sugiyama et al. [152] (Nippon Steel Corp.). It includes models for operational design, burden distribution, gas, solid and liquid flow, for the reaction rate of seven chemical reactions, for heat transfer and a total combination model. When operational conditions and a blast furnace profile are given, this model provides (1) streamlines of gas, liquid and solids, (2) pressure distribution, (3) reduction degree of iron oxides, (4) gas, solid and liquid temperature, and (5) location of the cohesive zone.

An integrated process computer system in the entire ironmaking department is being developed for increasing flexibility and productivity in the ironmaking systems which consist essentially of coke ovens, sintering machines, hot stoves, and blast furnaces.

The three-layer hierarchical system shown in Figure 102 is used for integrated control. In the system, *microcomputers* can accept the operating data directly from the plant and can control it. A *process computer* which eventually controls the overall ironmaking system is installed to provide sufficient information to the operator for realizing effective operation. Finally, a central *business computer* is connected to the process computers for optimal control of the overall iron and steel production system. Chiba works of Kawasaki Steel Corp. constructed this three layers system for two sintering plants and achieved effective operational control.

Although great progress has been made in the computer control of blast furnaces by introducing mathematical models, control is still incomplete. Recently, artificial intelligence has been introduced into blast-furnace control. The principal strategy of this technology is based on operational data [153]. Therefore, the question how to accumulate the operating data is most important. Some trials have been made to couple the artificial intelligence (Expert system) with a mathematical model.

Energy Recovery. After the oil crisis, energy cost increased drastically. Therefore in high-energy consuming industries, energy saving has been examined from various points of view. Energy saving and energy recovery are still conducted in each ironmaking process. In the blast furnace, a lot of energy is saved by using top-pressure recovery turbines. Figure 103 illustrates the development of energy savings in the ironmaking department of NSC between 1973 and 1985.

Energy recovery methods and energy network possibilities interconnecting the coking plant, sintering plant and blast furnace areas are illustrated in Figure 104 by the example of Thyssen Krupp Stahl AG [155]. Of decisive importance for the economic viability of investments aimed at energy recovery are the price of the primary energy to be replaced, the distance between supplier and consumer, the supply : demand ratio, and the extent of the necessary plant engineering.

The coke oven gas produced in the coking plant meets the requirement for gaseous fuel in the sintering plants, the rolling mill furnaces, in the coke plant, and partly of the power station – while blast furnace gas is partly used as an underfiring gas in the coking plant – for heating the blast furnace hot stoves and in the power plant.

Figure 104. Example for energy consumption and recovery at coke plant, sinter plant, and blast furnace

At the coke dry quenching facility (if available) preheated feed water from the power plant is converted into high grade steam and this, in turn, is used in a power plant turbine to generate electricity. It has to be noted, that in Germany it is today uneconomical to operate a coke dry quenching installation because the credits earned from the recovered energy are insufficient to cover the coke dry quenching installation's operating and capital costs. The dry coke quenching facilities are built because statutory requirements in Germany demand a low-emission quenching process, even if it was found that the emissions of a modern wet quenching system approximate the emission levels of a coke dry quenching installation [156].

In sintering plants the sinter cooler offers the simplest and most abundant potential for heat recovery. The recovered heat is used in the form of hot combustion air for use in the ignition furnaces and/or for heat supply to a hood downstream of the ignition furnace of the sinter plant. Such recovery systems are used in many sinter plants, for example, in Japan and Europe. As shown in the example of Figure 104, part of the heat can be recovered from air by means of thermal oil circulating in a finned-tube heat exchanger between the blower and stack and the combustion media of the hot blast stoves of the blast furnace can thereby be preheated. The combustion media of the hot blast stoves' are also preheated by the hot stoves waste gas by means of thermal oil. The flue gas' waste heat from the hot blast stoves can also be supplied to a municipal district heating network.

A further significant potential for energy recovery is the use of top pressure energy recovery turbines to exploit the pressure difference of blast furnaces operating with elevated top pressure. The use of top pressure energy recovery turbines at blast furnaces is also gaining in importance because of the steady rise in electricity prices. By this energy recovery approximately one-third of electricity required for blast compression can be recovered.

2.5.7. Hot-Metal Desulfurization

The sulfur content of the hot metal produced depends on the sulfur content of the reductants, the slag basicity, the slag volume, the silicon content of the hot metal, and the alkali load of the blast furnace. The sulfur transfer mechanism in the blast furnace is shown schematically in Figure 105. After the hot metal is separated from slag, the former is desulfurized by gas – metal and slag – metal reactions. However, in the upper part of the cohesive zone, the sulfur compounds present in the gas phase are absorbed partly by solid iron ores.

Figure 105. Schematic representation of sulfur transfer routes in the blast furnace [160] (Courtesy of The Iron and Steel Institute of Japan)

The steelmaking process requires a sulfur content of the hot metal of $< 0.025 - 0.035\,\%$, because desulfurization is difficult in the steelmaking process. Sulfur can be removed in the blast furnace, between the blast furnace and the steel shop, and in the steel shop. The cost is reported to be the lowest for desulfurization between the blast furnace and the steel shop [157].

Desulfurization in the *blast furnace* requires an increase in the limestone additions. This leads to the additional costs associated with the limestone itself and the increased coke rate because more heat is needed for melting the slag and for decomposing the limestone. In addition to this, the carbon dioxide generated from limestone must be compensated for. Limestone addition to the blast furnace can be avoided in certain limits if basicity and chemical composition of the sinter introduces all slag-forming components necessary for the burden. This saves coke consumption in the blast furnace because decompostion of limestone is transferred to the sinter plant.

Desulfurization in the *steel-producing vessel* requires a large slag volume even for highly basic slags because of the unfavorable sulfur distribution ratio under oxidizing conditions (see Section 2.2.2). Iron losses to the slag increase because of the large slag volume.

At present, it is advantageous to desulfurize at least a portion of the hot metal during *transportation to the steel shop.* After mixing with hot metal that is not desulfurized outside the blast furnace, an input sulfur content of $\leq 0.02\,\%$ can be delivered to the steel shop.

Desulfurizing Fluxes include *calcium compounds* which are in the solid state or half melting conditions at the hot metal temperature (e.g., CaO, CaC_2, $Ca(CN)_2$, and CaF_2), *alkaline compounds* in the liquid state (e.g., KOH, NaCl, and NaF), and *magnesium and its alloys* in the gaseous state. Their desulfurization ability is remarkably affected by treatment conditions such as (1) mixing, (2) atmosphere (oxidizing or reducing), (3) composition of hot metal, and (4) property and amount of blast furnace slag. Figure 106 shows the equilibrium sulfur content obtained by each desulfurizing flux. Actual desulfurization curves for the *bottom blowing* method with nitrogen are shown in Figure 107.

Figure 106. Temperature dependence of equilibrium sulfur content of carbon-saturated hot metal [158] (Courtesy of The Iron and Steel Institute of Japan)

Figure 107. Changes of sulfur content with time in bottom-blowing ladle desulfurization process for variable fluxes (amount of flux addition 10 kg/t hm) [158] (Courtesy of the Iron and Steel Institute of Japan)
● CaC_2; ▲ CaO; ■ $Ca(N)_2$; □ Na_2CO_3; △ NaOH; □ KOH; x NaCl; ▽ NaF; ▼ Ca F_2; ⬢ Na_3AlF_6

According to these figures, desulfurization degree, method, cost, and workability should be considered in addition to desulfurizing ability when selecting of a desulfurizing flux.

The equation for the desulfurization reaction with *soda ash* [159] and of concurrent reactions are as follows (Eq. 171 – 173):

$$(Na_2CO_3) + [S] + [Si] \rightarrow (Na_2S) + (SiO_2) + CO \quad (171)$$

$$(Na_2CO_3) + (FeS) + [Si] \rightarrow (Na_2S) + (SiO_2) + [Fe] + CO \quad (172)$$

$$(Na_2CO_3) + [Si] \rightarrow (Na_2O{\cdot}SiO_2) + C \quad (173)$$

Furthermore, Na_2CO_3 reacts easily with SiO_2 from the refractories forming $2Na_2O \cdot SiO_2$, $Na_2O \cdot SiO_2$, and $Na_2O \cdot 2SiO_2$. The vaporization loss of Na_2CO_3 is ca. 6 % at 1250 °C. This value increases to 35 % at 1350 °C, therefore the effect of desulfurization decreases sharply at temperatures >1300 °C. The disadvantages of desulfurization with soda ash are its corrosive action to the vessel lining and the environmental problems related to discarding slags which contain high alkaline contents. Environmental problems arise from sodium oxide-containing fumes and from the reaction of water with the sodium sulfide contained in the slag which produces hydrogen sulfide and sodium hydroxide.

The desulfurization reactions of hot metal with *calcium carbide* are as follows:

$$\langle CaC_2\rangle + [S] \rightarrow (CaS) + 2\,[C] \quad (174)$$

$$\langle CaC_2\rangle + (1/2)\,\{O_2\} \rightarrow \langle CaO\rangle + 2\,[C] \quad (175)$$

$$\langle CaC_2\rangle + (1/2)\,[O] \rightarrow \langle CaO\rangle + 2\,[C] \quad (176)$$

$$C + 1/2\,O_2 \rightarrow CO \quad (177)$$

As calcium carbide is easily oxidized (see Eqs. 175 and 176) the desulfurization should take place under controlled atmosphere. The reaction product CaS which has a high melting temperature of 2450 °C forms the solid slag. The diffusion of sulfur in the hot metal to the boundary between hot metal and calcium carbide is the rate-determining step of the desulfurization reaction. In the sulfur-transfer mechanism, mixing strongly affects the degree of desulfurization. When calcium carbide particles are injected with an inert carrier gas, a calcium sulfide layer grows at the outer surface of the particle as the reaction proceeds. The reactivity of each particle decreases with increasing thickness of this layer. Thus, the efficiency of this flux is relatively low. Its advantage is that a very low residual sulfur content of the hot metal can be achieved irrespective of its initial sulfur content.

When *lime* is used, the following desulfurization reactions proceed:

$$4\,CaO + 2\,[S] + [Si] \rightarrow 2\,CaS + 2\,CaO{\cdot}SiO_2 \quad (178)$$

$$2\,CaO + 2\,[S] + [Si] \rightarrow 2\,CaS + SiO_2 \quad (179)$$

The reaction given by Equation (179) occurs at 1300 °C even if the silicon content of the hot metal is only 0.05 %. If the silicon in the hot metal is oxidized to silicon dioxide in this process, it reacts with lime to form $2CaO \cdot SiO_2$. This reaction decreases the amount of lime available for desulfurization. Therefore, oxidation of silica should be prevented by using the inert or reducing atmospheres or airtight vessels.

Magnesium is sometimes used as a desulfurizing flux because it has a very strong affinity for sulfur. Equations (180), (181), and (182) represent the desulfurization by magnesium and the oxidation of magnesium which occurs in the desulfurization process.

$$\{Mg\} + [S] \rightarrow MgS \quad (180)$$

$$\{Mg\} + [O] \rightarrow MgO \quad (181)$$

$$\{Mg\} + (1/2)\,O_2 \rightarrow MgO \quad (182)$$

The vaporization temperature of magnesium is relatively low (1107 °C). Therefore, magnesium evaporates upon contact with the hot metal and the desulfurization efficiency decreases. It is therefore necessary to control the vaporization (see below).

Desulfurization Processes. To produce low-sulfur or ultra-low sulfur steel, a number of desulfurization processes have been developed. Typical processes for desulfurization *outside* the blast furnace are listed in Table 31. In each process, acceleration of the desulfurization reaction is achieved by increasing the contact area between the desulfurizing fluxes and the hot metal. This is carried out by employing improved stir-

ring techniques. The other requirements for the processes are as follows: (1) inexpensive desulfurizing fluxes, (2) high reproducibility with regard to the degree of desulfurization, (3) small decrease of the hot metal temperature, (4) low iron loss to the slag, and (5) an easy and inexpensive disposal of the slag.

Table 31. Typical desulfurization processes outside the blast furnace [104] (Courtesy of The Iron and Steel Institute of Japan)

Method	Process
Soda-ash paving	soda-ash paving process
	reladling process
	ladle with siphon process
Shaking ladle	shaking ladle process
	DM converter process
	rotating drum process
Stirrer	Demag-Östberg process
	Rheinstahl process
	KR process
Injection	(ladle process)
	(torpedo-car process)
Gas bubbling	bottom blowing process
	top blowing process
Gas-lift mixing reactor	GMR process
Desulfurization with magnesium	injection process
	plunging bell process
Continuous desulfurization in the blast-furnace runner	turbulator process
	powder injection process
	paddle-type stirrer process
	electromagnetic stirrer process

Desulfurization in the *blast-furnace runner* is not widely accepted at present despite the favorable surface : volume ratio and the low degree of technical expenditure required. The reasons are the corrosive attack of the slag on the runner material, the hazardous exposure of the workers to alkaline fume, and the poor reproducibility with respect to the degree of desulfurization.

The soda-ash paving method is frequently used for desulfurization in the *transport ladle* because of its simplicity. The transport ladle is used to transport the hot metal from the blast furnace to the hot-metal mixer located in the steel shop. In this method, the desulfurizing flux is placed in the ladle prior to filling it with hot metal. Good mixing is achieved by formation of carbon dioxide and by the falling hot-metal stream. The slag is removed from the filled ladle. Figure 108 illustrates the relationship between the final degree of desulfurization and the amount of soda ash added. The final desulfurization degree increases with increasing soda-ash addition up to a value of 80 %, which is obtained at 8 kg "soda-ash addition" per tonne of hot metal. After that the desulfurization degree in most cases reaches a plateau level.

Figure 108. Effect of the amount of soda ash addition on the desulfurization of hot metal in various desulfurization processes [161] (Courtesy of Verlag Stahleisen mbH)

S = pig iron for steelmaking; Th = Thomas pig iron; F = pig iron for foundry
a) Ladle with siphon; b) furnace-runner and transportation ladle

Efforts to improve the mass transfer of the sulfur by moving the vessel containing the hot metal involved trials with *rotating drums* (Kalling – Domnarvet process [162]) and *shaking* or *rotating ladles.* In the shaking ladle, the ladle axis rotates around a circular path at ca. 70 rpm. By reversing the direction of the movement, the mixing effect can be enhanced (Kobe Steel process [160]).

Figure 109 shows desulfurization processes with mechanical stirrers. The stirrer proposed by Östberg (see Fig. 109 A) has a *hollow* stirrer which discharges the *hot metal* through horizontal tubes by centrifugal forces and absorbs hot metal from the bottom of the vertical tube. The simple stirrer proposed by Kraemer in Rheinstahl Hüttenwerk (Fig. 109 B) is made of refractory. This stirrer mixes *desulfurizing fluxes* into the hot metal. The stirrer developed by Nippon Steel (Fig. 109 C) is an impeller which produces eddy flow of the *hot metal.* Results of plant experiments for this stirrer are shown in Figure 110. According to this figure the process is highly effective for desulfurization. The stirrer method is widely used in North America, Eu-

rope, and Japan for the production of low-sulfur steel or ultra-low sulfur steel.

[S] Content before treatment (1350 °C): ○ 0.02 %; × 0.03 %; ● 0.04 %

The *injection method* of hot metal desulfurization is widely accepted for the desulfurization in a ladle or a torpedo-car. In this method the flux powder of desulfurization is injected with a gas stream. As flux powder CaC_2, $Ca(CN)_2$, CaO and soda ash are widely used. Magnesium is also used. The injection lance is better for dipping into the hot metal bath. The dipping depth should be 1/2 to 3/4 of the bath depth. NSC [164] and TSAG [165] developed the respective process for desulfurization by using the injection method.

Figure 111. Desulfurization ladle with porous plugs [166] (Courtesy of The Iron and Steel Institute of Japan)
a) Surface of hot metal; b) Porous plugs

In the *gas-bubbling* method, the desulfurizing flux is at first added to the surface of the hot metal and then mixing is started by the injection

of gas into the hot metal. The injection is made through the lance dipped into the hot metal (top-blowing method) or through the porous plug at the bottom (bottom-blowing method). Figure 111 represents schematically the bottom-blowing desulfurization ladle. Ultra-low sulfur steel containing 0.001 – 0.002 % S can only be produced by this method if the second addition of calcium carbide is made after the slag of the first treatment is removed.

The *gas-lift mixing reactor* method (GMR method) was proposed by Kobe Steel. The basic principle of this method is to use the buoyancy force of the gas injected at the bottom of the riser as driving force for a circulatory motion of the hot metal as illustrated in Figure 112. This method removes sulfur in hot metal to $<$ 0.002 % by adding 5 kg of CaC_2 per tonne of hot metal.

a) Dust collecting duct; b) Compressed nitrogen; c) Inlet of flux; d) Cover for dust catch; e) Desulfurizing flux; f) Hot metal; g) Ladle; h) Main part of gas-lift mixing reactor

If magnesium is used as a desulfurizing flux, magnesium – coke [168], a plunging bell [168 – 170] injection of a magnesium – aluminum alloy, surface-coated magnesium, or a mixture of CaO and Mg with gas [171 – 173] are used to suppress the vaporization loss of magnesium.

Since some problems remain unsolved in magnesium desulfurization (such as violent scattering of hot metal and resulfurization which requires a treatment time that is too long), the operation techniques must be improved. The advantages of this method in comparison to other methods are the very small amounts of flux required, ca. 1 kg/t, and the easy disposal of the slag.

It is very difficult to compare the various desulfurization processes for the pretreatment of hot metal, because many factors such as facility cost, operation cost, amount and cost of desulfurizing flux, degree of desulfurization, workability, and iron loss must be considered. Figure 113 shows the relationship between degree of desulfurization and operation cost. To reduce the cost of desulfurization, effective and inexpensive desulfurization fluxes and desulfurization processes requiring less flux must be developed.

2.6. Direct Reduction Processes

The distinctive features of the individual processes have already been described in Section 2.4.

The name "direct reduction" is misleading, because these reduction processes do not consti-

tute a "more direct" route to steel than does the blast furnace. Nor does the term have anything to do with direct reduction in the blast furnace. Despite all these objections, however, the term has become accepted in international usage.

Table 32 lists the plants for direct reduction of iron ore that were in operation or under construction in 1995, together with their locations and the processes employed.

Table 33 contains technical data for the direct reduction processes described in this chapter and certain other processes. The stated capacities should be regarded as approximate, as some of the processes have been further developed. The annual plant outputs often vary from the original design capacity. In particular, the demand of the client (i.e., of the electric steel mill), a low scrap price, natural gas supply, or a shortage of spare parts may lower the annual output.

In most direct reduction processes, up to 92 – 95 % of the iron oxide is reduced to metallic iron. The degree of metallization $Fe_{metallic}/Fe_{total}$ in % is an important variable for characterizing the direct-reduced iron (DRI) produced by the process in question.

2.6.1. Shaft Furnace Processes for Direct Reduction

Wiberg – Söderfors Process. The oldest shaft furnace process for direct reduction of iron ore, the Swedish Wiberg process, is based on a patent issued in 1918. Up to the end of the 1950s, it was technologically improved and adapted to changed conditions on the ore and fuel markets. Nowadays, the Wiberg process is only of historical significance.

The development of the process was promoted above all by the growing shortage of very low-sulfur charcoal pig iron, the raw material for swedish high-quality steel. In addition, it was intended that coke would only be used for the reduction process, the process heat being supplied by cheap electricity available because of the local conditions.

In the Wiberg process (Fig. 114) the iron ore is preheated in the top section of the furnace (a) to the reduction temperature of ca. 950 °C by hot gases generated by combustion of part of the so-called excess gas. In the zone immediately below, the ore is reduced to wustite with ca. one-third of the reducing gas volume. The reduction to metallic iron takes place in the bottom section of the furnace at ca. 950 °C with ca. 1300 m^3 (STP) gas/t DRI.

Two thirds of the reducing gas are withdrawn by means of a hot gas fan (e) and regenerated in the carburetor (b) over a hot layer of coke. The energy required for the endothermic reactions

$$CO_2 + C \rightarrow 2\,CO$$

$$H_2O + C \rightarrow CO + H_2$$

is supplied by resistance-heating electrodes.

The gas, which is contaminated with sulfur from the coke, is passed through dolomite in a shaft furnace for desulfurization (c). The reducing gas contains 95 % carbon monoxide and hydrogen in a ratio of ca. 3 : 1.

The Wiberg process, which was developed for the special conditions of the Swedish iron industry, was a pioneering technology. The high cost of coke and electrical energy to generate the reducing gas is the reason why this process is no longer in use.

The principle of generating the reducing gas by a chemical reaction between the off-gas of the reduction shaft (the top gas) and natural gas has been applied in two processes: the Purofer and the Midrex process.

Purofer Process. This process (Fig. 115) was developed at Hüttenwerke Oberhausen (later Thyssen Niederrhein); the ICEM process developed by the Romanian Research Institute for Metallurgy is similar to it. The ore (preferably pelletized) passes vertically downward through the shaft furnace in countercurrent to the hot reducing gas. The gas is used for heating the charge and for reduction. The reducing gas is generated catalytically in regenerative-type gas generators. After cooling and purification, the top gas is used partly for heating the gas generators and partly for chemical conversion of the natural gas at 900 – 1000 °C to reducing gas according to the equations

$$CH_4 + CO_2 \rightarrow 2\,CO + 2\,H_2$$

$$CH_4 + H_2O \rightarrow CO + 3\,H_2$$

The carbon from methane reforming that is deposited on the catalyst of the regenerator during reducing-gas production is burned off during heating-up. This regenerative phase causes slight variations in reducing gas temperature and composition. In the Purofer process, the DRI is discharged hot and can be transported in containers either directly to an electric steel mill or to a hot briquetting plant.

In addition to the pilot plant in Oberhausen (capacity 500 t/d), one plant was built in Brazil (but with a Texaco heavy-oil gasifier as gas generator), which is now dismantled. The only plant in operation in Iran is designed for operation with natural gas.

Midrex Process. The most successful gas-based direct reduction process is the Midrex process developed by Midland-Ross Corp. of Toledo, Ohio (see Fig. 116) [175].

In this process, natural gas continually undergoes catalytic conversion to hydrogen and carbon monoxide (ratio ca. 1.5 : 1) at ca. 900 °C using part (ca. 2/3) of the top gas, which is cleaned and cooled to lower its water-vapor content. Reduction is accomplished in the cylindrical part of the shaft furnace at 780 – 900 °C, depending on the temperature at which sintering ("sticking") of the reduced ore or the pellets occurs. In the conical discharge section of the shaft furnace, the DRI is cooled to ca. 45 °C by recirculated cooling gas. Here the carbon content of the

product can also be adjusted to between 1.2 and 2.5 %. There are also Midrex plants featuring hot discharge followed by hot briquetting.

One-third of the top gas is used to heat the gas reformer, whereas the hot flue gases serve to preheat the combustion air and the feed gas mixture prior to reforming.

With increasing heat recovery in the recuperator and reduction temperatures of ca. 900 °C, energy consumption per tonne of DRI may fall to 9.6 GJ in the Midrex process.

The reducing gas can also be generated by *steam reforming* of natural gas. The first shaft furnace direct-reduction process to employ steam reforming was the *Armco process.* Here natural gas undergoes continuous catalytic conversion with excess steam according to the reaction:

$$CH_4 + x\,H_2O \rightarrow CO + 3\,H_2 + (x-1)\,H_2O$$

After removal of the water vapor, the top gas is used as cooling gas.

Only one commercial plant was ever built because of the difficulty of achieving complete mixing of the cooling gases entering the lower part of the shaft with the hot top gases from the reduction zone, the low reducing potential of the gases, and a range of technical problems.

Nippon Steel (NSC) Process. The reducing gas containing over 95 % carbon monoxide and hydrogen is generated by steam reforming with only a slight excess of water vapor and addition of top gas freed from water and carbon dioxide (see Fig. 117). Like the Purofer process, the NSC process has a hot discharge facility, from which DRI can be filled into containers and taken either directly to a steel mill or to a hot briquetting plant. Only one plant in Malaysia with a design capacity of 1000 t/d was built which was later modified to a HyL plant.

HyL-III Process. Hojalata y Lamina S.A. (HyL) of Mexico has also developed a shaft-furnace process based on steam reforming of natural gas (HyL-III process, Fig. 118). This process represents a further development of HyL's retort process (see Section 2.6.2). Because of the large quantity of excess steam produced by continuous catalytic conversion of the natural gas, the generated gas must first be cooled to remove the excess water vapor. After addition of water- and carbon dioxide-free top gas and indirect heating to ca. 850 °C, the reducing gas is fed into the reduction shaft. In the bottom section of the shaft furnace, the DRI is cooled down to $<$ 50 °C as in the Midrex process. HyL-III plants can also be operated with hot discharge and hot briquetting.

ranges from 92 – 95 %. The carbon content is usually 1.5 – 2 %.

2.6.2. Retort Processes

HyL Process (Hyl-I Process). A number of plants employing this process were built until 1975 before the shaft-furnace processes became established. The development of this process began in 1951 at Hojalata y Lamina S.A., Monterrey (Mexico). It operates with four reactors simultaneously, each one being at a different point in the reduction cycle at a particular time. Fig. 119 shows the stage at which fully reduced DRI is cooled with cold reducing gas in retort I. At this point, the carbon content of the DRI is adjusted to ca. 2 %. After cooling and water-vapor condensation, the off-gas from this retort is reheated to reduction temperature and passed through retort II, where pre-reduced material is fully reduced. The gas is then recooled to remove any newly formed water vapor, reheated

and fed to retort III containing freshly charged ore, which is then pre-reduced. The off-gas from this stage is cooled and freed from water vapor; it is then available for use as fuel gas for steam raising. Retort IV is simultaneously emptied from DRI and charged with ore.

As lump ore or pellets are stationary in the retorts during reduction, the risk of sticking is high. Sophisticated removal devices are required for emptying the retorts.

The degree of metallization of the DRI is often lower at the bottom of the retorts than in the upper layers. Thus the target average degree of metallization is often only ca. 86 %. As gas generation is carried out with a large excess of steam and cooling and reheating of each retort is very costly, an energy consumption of ca. 21 GJ per tonne DRI must be taken into account.

Höganäs Process. This process has been in operation since 1911 and has undergone no significant technical modifications since the 1950s, nor has its use become any more widespread. In this process, iron ore is reduced with coal in hermetically sealed crucibles with indirect heating (by combustion of the carbon monoxide escaping from the crucibles). The sulfur content of the DRI is minimized by adding limestone or dolomite to the charge mix and rapidly cooling the product. It is thus suitable for use in powder metallurgy or stainless-steel production. The capacity of plants operating on the Höganäs process is relatively low, ca. 35 000 t/a.

Kinglor – Metor Process. This process occupies a category between the shaft furnace and the retort processes. The development of this process (Fig. 120) by Co. Kinglor – Metor S.p.a., Mineraria & Metallurgica, Italy, began in 1971 but was based on the Echeverria process which had been in operation in Spain since 1957 [176]. Like the rotary kiln processes (see Section 2.6.4) and in contrast to the gas-based direct reduction processes described so far, it uses a solid carbon-containing reductant, which is charged together with the ore (6 – 25 mm size) and, where applicable, limestone or dolomite is used for desulfurization. The heat for the strongly endothermic reaction

$$FeO_x + x\,C \rightarrow Fe + x\,Co$$

which in this case takes place at ca. 1050 °C, is supplied through the wall of the shaft furnace, which must therefore have a high thermal conductivity. Silicon carbide satisfies the requirements as to thermal conductivity, heat resistance, and abrasion resistance. The shaft heating burners are designed for gaseous and liquid fuels. The reduced material is indirectly cooled with gas in the bottom zone of the shaft. Commercial plants consist of a group of six reduction chambers, each with a capacity of ca. 20 t/d DRI.

2.6.3. Fluidized-Bed Processes

Fluidized-bed processes for direct reduction exploit the lower cost of fine ores compared with lump ores and pellets. However, the disadvantages of these processes are that (1) the fine ores have a tendency towards sticking above ca. 700 °C and that (2) below 600 °C the susceptibility to reoxidation of the DRI is so high that it must be stored under inert gas or hot-briquetted.

Fluidized-bed processes that operated with pure hydrogen were the *Novalfer process* and

the *H-Iron process;* however, they did not attain any major technological significance. In the *HIB-process,* reduction was carried out in several stages with a gas containing ca. 85 % hydrogen. The ore of 0 – 2 mm size underwent only ca. 65 % metallization and was then hot-briquetted. The sole commercial plant has been converted by Midrex into a shaft furnace plant with hot discharge – hot briquetting.

Fior (Fluidized Iron Ore Reduction) Process. Development of the Fior process (Fig. 121) started in the 1950s at Esso Research and Engineering in collaboration with Arthur D. Little. Following the building and operation of a 300 t/d pilot plant in Dartmouth, Nova Scotia, from 1965 to 1969, a 400 000 t/a commercial plant operating on this process was built in Puerto Ordaz, Venezuela.

Figure 121. Schematic of the Fior process
a) Reformer; b) Gas cooler; c) Heater; d) Fluidized-bed reactor; e) Scrubber; f) Stack

After drying and preheating to ca. 880 °C, the fine ore (mostly < 5 mm) is metallized to a degree of ca. 92 % in a three-stage fluidized bed. The reducing gas is generated by steam reforming of natural gas in continuously operating catalytic reformers. The reduced fine ore is hot-briquetted, the briquettes being cooled and shipped to the end-users without further passivation.

The *Finmet process* is a further development of the Fior process, taking advantage of the experience gained in more than ten years of Fior plant operation.

Iron Carbide Process. In the Iron Carbide process developed by Stephens (Iron Carbide Holding Ltd.) (see Fig. 122) fine-grained iron oxide (0.1 – 1 mm) is reduced by a gas containing hydrogen and methane to give iron carbide [210]

$$3\,Fe_2O_3 + 5\,H_2 + 2\,CH_4 \rightarrow 2\,Fe_3C + 9\,H_2O$$

A 300 000 t/a iron carbide plant is operated in Trinidad by a joint venture of NUCOR and SAMITRI.

The iron oxide is heated to 700 °C (Fig. 122 a) and then fed to the fluidized-bed reactor (b), where reduction of the oxide and formation of iron carbide occurs at ca. 570 °C and ca. 4 bar.

The fluidized-bed reactor is equipped with baffles which effect movement of the solids from the inlet to the outlet. The relatively low reduction temperature required to form iron carbide resulted in a retention time of about 16 h in the first 900 t/d plant built in Trinidad. Due to a high gas : solids ratio of about 10 000 m^3 (STP) per tonne oxide, much larger gas volumes must be handled than in shaft furnace processes.

The fines carried over with the reduction gases are partially recovered in a cyclone (c) and recycled to the reactor. After heat exchange with the cold reduction gas (d) the off-gases are scrubbed, cooled for condensation of water (e), compressed, and recycled to the process via heat exchangers and a gas heater (h). Make-up gas is hydrogen. The reduction gas consists of 60 % CH_4, 34 % H_2, 2 % CO, 1 % H_2O, and minor amounts of CO_2 and N_2. The iron carbide formed in NUCOR's plant contains 90 % total iron (90 % as Fe_3C, 8 % as FeO, 2 % as metallic iron), 6.2 % C, and 2 % gangue.

Iron carbide is categorized as a nonpyrophoric material, therefore handling and ship-

ping do not require briquetting or other treatment to avoid reoxidation.

Circored Process. In the Circored process (see Fig. 123) developed by Lurgi [211] small-size iron oxide ores (0.1 – 1 mm) are reduced by hydrogen according to

$$Fe_2O_3 + 3\,H_2 \rightarrow 2\,Fe + 3\,H_2O$$

The ore is preheated to ca. 900 °C and first prereduced to about 65 % metallization in a circulating fluidized-bed reactor (CFB) within 20 min.

Final reduction to 90 – 93 % metallization is accomplished at lower gas velocities in a subsequent bubbling fluidized-bed reactor (FB) with several compartments. This step requires up to 4 h, depending on the desired metallization and the reducibility of the oxide. The reactors are operated at temperatures generally below 650 °C to avoid sticking. The off-gases from the final reduction step in the FB and make-up hydrogen are passed into the CFB reactor. Most of the solids in the off-gases from the CFB are recovered in the recycle cyclone. The gases are then led through a heat exchanger, dedusted, cooled for condensation of water and compressed to the plant pressure of ca. 4 bar. After heat exchange with the hot off-gases from the CFB the reduction gas is heated to 750 °C before being reintroduced to the two reduction reactors.

Before entering the CFB, hot make-up hydrogen is used to transport the reduced fines from the FB to a briquetting plant and to heat them up. The reduced DRI fines are hot-briquetted, if the product is intended for export. It can also be charged directly into smelting furnaces.

A 500 000 t/a Circored plant is currently being started up in Trinidad.

The use of hydrogen as a single reductant source leads to the fact that no carbon is present in the Circored product. By introduction of hydrocarbons into the product stream after the final reduction stage the Circored process can also be applied for production of a carbon containing hot briquetted iron (HBI) with ca. 1 % carbon.

Circofer Process. The Circofer process (see Fig. 124) is another fluidized-bed process developed by Lurgi Metallurgie. This process also

Figure 123. Flow sheet of the Circored process
a) Oxide heater; b) Circulating fluidized bed; c) Cyclone; d) Heat exchanger; e) Scrubber/cooler; f) Compressor; g) Gas heaters; h) Fluidized bed; i) Briquetting machine

operates with a CFB prereduction and a final FB reduction step and is based on coal as the reductant and basic energy source. Fine coal is partially burned in a heat generator and the semi-coke produced is used both as a heat carrier to transfer heat to the CFB and to prevent sticking of the iron particles at the reduction temperature of > 900 °C. Final reduction is accomplished at lower temperature in the FB with recycled off-gases from the CFB. Gas treatment is similar to that in the Circored process. In the Circofer process, however, a CO_2 absorber step had to be included, because reduction is mainly effected with CO containing gases. A 5 t/d pilot plant is operating at Lurgi's R & D center in Frankfurt.

2.6.4. Rotary Kiln Processes

Rotary kiln processes for direct reduction of iron oxides are based on *coal* as reductant. Typical features of rotary kiln processes are their high flexibility with regard to feedstocks and their capability for economic production of even small quantities of DRI. All non-caking coals ranging from lignite through bituminous coals up to anthracite or coke breeze are suitable as reductants. In addition to the pellets and lump ores that are the main iron-bearing materials, iron sands, and ilmenite concentrates are also industrially used.

Of the various rotary kiln processes [177], the has attained the greatest technological significance, and most of the DRI currently produced in rotary kilns worldwide is manufactured by the SL/RN process (see Table 33). Therefore, the principle of the rotary kiln processes will be explained with reference to this process. The fundamentals of the reduction mechanism are dealt with in Section 2.4.

The SL/RN Process. The SL/RN process was developed in 1964 out of the combination of two separate processes: the Stelco – Lurgi (SL) process for producing DRI from *high-grade ores* and the Republic Steel – National Lead (RN) process for beneficiation of *low-grade ores.*

In the SL/RN process (Fig. 125), reduction of iron oxide is carried out in a refractory-lined

Figure 124. Flow sheet of the Circofer process

rotary kiln (f) inclined from the feed to the discharge end. The slope of the kiln is ca. 1.5 – 2.5 % depending on the feed materials.

The kiln is equipped at both ends with special seals between the rotating kiln and the fixed feed and discharge heads. These seals essentially prevent inleakage of air and thus reoxidation. A number of fans are installed on the shell of the kiln; these supply the necessary process air via so-called air tubes or via air injection nozzles in the feed zone of the rotary kiln.

The *internal kiln temperature* is continuously recorded by thermocouples installed along the entire length of the kiln and projecting into the kiln freeboard. The *power supply* to the shell fans and the transmission of the data recorded by the individual thermocouples is accomplished by means of slip rings mounted on the kiln shell. Devices for taking samples of material during operation are also mounted on the kiln shell.

The *central burner* installed at the kiln discharge end is used to dry out the kiln refractory lining during the initial startup and to heat up the system after a shutdown. Under normal operating conditions, only air without fuel is fed through the central burner. However, if low-reactivity coals (anthracite) are used, it may be necessary to continuously fire a small amount of supplementary fuel via the central burner to satisfy the overall heat requirement.

Fresh coal, recycle carbon (char), ore or pellets, and dolomite or limestone as desulfurizing agent are charged in a predetermined ratio at the kiln feed end by a gastight charging system.

Up to ca. 35 % of the total fresh coal required is fed into the kiln from the discharge end with a special pneumatic injection system (h). This improves the utilization of the energy contained in the coal volatiles and prevents depletion of carbon in the material bed, especially in the case of very long kilns.

The charge passes through the kiln in ca. 8 – 12 h. The retention time mainly depends on the slope, degree of filling, and the rotational speed of the kiln. For each combination of iron-bearing material and reductant, a minimum retention time is necessary to achieve the desired degree of metallization; this is determined with laboratory tests. For example, the necessary retention time for a combination of "porous" pellets and highly reactive lignite is low, whereas that for "compact" lump ores and low-reactive anthracite is high.

In simplified terms, the rotary kiln can be divided into a preheating and a reduction zone (see Fig. 126).

Figure 126. Temperature and degree of metallization as a function of the location in the kiln
a) Gas temperature; b) Charge temperature; c) Metallization

In the *preheating zone,* the feed materials are dried, and coal volatiles escape, and the charge is heated to reduction temperature (ca. 950 – 1100 °C).

An overview of the coals and ores used in SL/RN plants is given in Table 34. The usual grain sizes of the feed materials are < 15 mm for the reductant, < 25 mm for the iron-bearing materials and < 3 mm for the desulfurizing agent.

The charge is heated through exchange of heat with the kiln waste gases flowing countercurrently to the charge. The energy is supplied by the sensible heat of the waste gases from the reduction zone, by the partial combustion of the coal volatiles, and by direct burning of carbon in the preheating zone.

If high-volatile coals are used, injection of air into the charge can bring about partial combustion of the volatiles within the charge, which accelerates preheating.

In the preheating zone, a certain degree of prereduction is accomplished through the coal volatiles. However, the greater part of the reduction occurs in the *reduction zone* at near-constant temperature according to

$$Fe_xO_y + CO \rightarrow Fe_xO_{y-1} + CO_2$$

Table 34. Iron ores and coals processed in SL/RN plants

* Prereduction only.

The carbon dioxide formed during reduction reacts within the charge with fixed carbon according to the Boudouard reaction

$$C + CO_2 \rightarrow 2\,CO$$

and forms the carbon monoxide required for the reduction process.

The necessary heat in the reduction zone is supplied through combustion of the surplus carbon monoxide from reduction, of the volatiles in the injected coal, and of fixed carbon.

The desired temperature profile is established by controlled addition of combustion air along the length of the kiln.

Inside the kiln, an *oxidizing atmosphere* above the charge and a *reducing atmosphere* within the charge prevail in close proximity (see Fig. 127). Accordingly, the reactions occurring above the charge in the kiln freeboard are exothermic and those taking place in the material bed are endothermic. Separation of the two atmospheres is ensured by the gas generated in the material bed, which also prevents reoxidation of particles of DRI at the charge surface.

After leaving the rotary kiln, the DRI is cooled to ca. 100 °C together with the excess coal in an indirectly cooled rotary cooler. The DRI is separated from the nonmagnetic kiln discharge material by *screening* and *magnetic separation.*

The > 3 mm fraction of the *magnetic portion* can be directly used for steel production, the < 3 mm fraction is normally briquetted before further use.

The > 3 mm fraction of the *nonmagnetic portion* is mostly char and can be recycled to the process. The < 3 mm fraction, containing ash, calcined desulfurizing agent, and char, is disposed of.

In particular cases, e.g., if the ash content of the coal is very low, it is advantageous to charge the entire kiln discharge material directly into a downstream electric furnace without cooling and separation. This brings considerable savings in electric energy for the melting down process.

The waste gases leave the kiln at the feed end at ca. 850 – 1000 °C. They pass through a dust-settling chamber to remove coarse dust and enter an afterburning chamber, where combustible gases and carbon particles are burnt off. The waste gases are then cooled, cleaned and discharged to the atmosphere. Alternatively, the sensible heat of the gases leaving the afterburning chamber may be recovered in a downstream steam boiler for generation of process steam or combined for production of steam and electric power.

Since 1984, a four-strand SL/RN plant with a capacity of 600 000 t/a DRI and waste-heat recovery has been in operation at the Vanderbijl-

Figure 127. Gas composition in the kiln freeboard (A) and kiln charge (B) measured in an industrial kiln of 50 m length

park Works of ISCOR in South Africa. Approximately 1.9 t of process steam (1.6 MPa, 260 °C) per tonne of DRI are generated for the steel mill. In 1993 a second 150 000 t/a SL/RN plant with waste-heat recovery for power generation was installed in Champa, Maharashtra, India. This plant was extended by an identical unit in 1996.

Taking into account a variety of reducing agents, the energy requirement (without char recycling) referred to as the lower heating value of the coals, is ca. 19.3 GJ/t DRI for lignite briquettes (A), ca. 18.4 GJ for bituminous coal (B), and ca. 17.8 GJ for a mixture consisting of 70 % anthracite (C) and 30 % bituminous coal (B) [178]. The analyses of these coals are shown in Table 35.

If a combination C : B = 50 : 50 with recycled char is used, the energy requirement is only 14.8 GJ/t DRI [178].

Further typical consumption figures are given below:

Ore or pellets (Fe_{tot} 67 %), t	1.42 – 1.44
Fixed carbon, kg	380 – 475
Electric power, kWh	70 – 90
Water, m^3	1.5 – 2.5
Manpower, man hours	0.4 – 0.6
Repair and maintenance, $	8 – 10

In addition to DRI production, SL/RN rotary kilns are commercially used for *prereduction* of iron ore at Highveld Steel in Witbank, South Africa (13 units with an ore capacity of 200 000 t/a each, 30 – 35 % metallization) and for reduction of *ilmenite concentrates* at Westralian Sands Ltd, Capel, Western Australia (two units, total ilmenite throughput ca. 480 000 t/a) and at TIWEST, Chandala, Western Australia (one unit, ilmenite throughput ca. 300 000 t/a).

2.7. Smelting Reduction Processes

In smelting reduction processes hot metal is produced directly with coal, particularly noncoking coal.

The main reasons for developing smelting reduction processes (since 1970) was to find processes which produce liquid iron economically at low capacity and use coal directly. The processes should be more flexible regarding raw material and operation and should cause less pollution than a blast furnace including coke making.

The ore, fine ore, or lump ore is *prereduced* with the gas produced in the melting vessel. The prereduced ore (sponge iron) is melted down in a melting vessel where melting energy is generated by oxidation of coal. Some processes use also electrical energy in the melting stage.

The principles of the *prereduction stage* (shaft furnace or fluidized bed) are given in Sections 2.2 and 2.3 and the thermodynamic principles for the final *melter stage* are presented in Section 2.3.

Simulations with computer models were performed for different smelting reduction process configurations [179 – 181] to find an optimum process and to estimate the influence of post-combustion and prereduction on coal consumption. (Post-combustion is defined as the partial oxidation of a gas previously generated in the melting vessel, whereby the energy produced

Table 35. Coal analyses

Coal	A	B	C
Fixed carbon, %	44	59	88

Ash, %	5	14	4
Lower heating value (dry), GJ/kg	23.3	27.0	32.7

by this combustion is transferred to the bath with high efficiency.) Economical and technical comparison can be found in the literature [182 – 184].

2.7.1. Characteristics of Coals for the Smelting Reduction Processes

The most important property of the coal for the smelting reduction processes is its volatile content, because this determines the gasification temperature of the reaction

$$\text{Coal} + \text{Oxygen} \rightleftharpoons \text{Carbon monoxide} + \text{Hydrogen}$$

Coals with *low volatile* content generate a high temperature when gasified with oxygen, the released energy being used for sponge iron melting. Gasification of coals with a *high volatile* content such as lignite results in a low temperature because the volatile hydrocarbons must be cracked before gasification can occur.

Figure 128 shows the calculated adiabatic gasification temperature (gasification to $CO + H_2$) as a function of the H : C and O : C molar ratio of the coal. The higher the gasification temperature the better the coal is suited for smelting reduction process, i.e., the lower is the coal consumption. The classification of coals by the aforementioned molar ratio is more accurate than by volatile content because coals with the same volatile content can show remarkable differences in their gasification temperature. The coal rank classification shown in Figure 128 gives only a rough estimation.

For *converter-type melters* the degree of post-combustion must be increased when using high-volatile coal, but there are some limitations with respect to the movement of the bath. For processes with countercurrent flow of coal and gas, besides energetic limitation, problems with tar formation can also occur.

Figure 128. Adiabatic gasification temperatures ($H_2 + CO$) for coals in dependence on the atomic number ratio
a) Lignite; b) Subbituminous coal; c) High volatile bituminous coal; d) Medium volatile bituminous coal; e) Low volatile bituminous coal; f) Anthracite; g) Coke

The *ash content* of the coal is less critical than its volatile content. The mainly acidic ashes of the coal must be compensated for by additives so that basic slags can be formed. Thus, processes which require a high slag basicity are more sensitive to the ash content. The additives (limestone, dolomite) enter the melter stage in most cases in the calcined form. Otherwise the influence of the ash content on the coal consumption is too high and extra energy for calcining the additives and for the endothermic Boudouard reaction is needed.

The *moisture content* of the coal (ca. 10 %) decreases the gasification temperature drastically because of the endothermic water – gas reaction. Hence, most of the processes use dried coal.

Other properties of the coal such as the melting behavior of the ash, the swelling index, or the reactivity are of little or no concern. The Hardgrove index influences the grinding cost when grinding is necessary (converter processes).

The *sulfur content* of the coal should be of course as low as possible (≤ 1 %). However, the tolerable range must be evaluated for each smelting reduction process separately.

Table 36. History of smelting reduction processes from 1970 to 1990 [184]

Process	Ore type	Fuel	Prereduction (reduction degree)	Final reduction	Development stage	References
Char or coke bed melter – gasifier						
KR/Corex	lump	lump coal	shaft furnace (90 %)	melter	1000 t/d	[186 – 189]

2.7.2. Classification of Smelting Reduction Processes and Earlier Developments

The first developments in smelting reduction on a laboratory scale failed in the 1960s because the conversion of coal and fine ore in a melting vessel was tried without prereduction [185]. The next development was in Sweden in the 1970s, where the energy was introduced into the melting vessel in the form of *electrical energy.* Further developments were the *converter processes* with and without post-combustion. Processes which are closest to the blast furnace are those with a char-or coke-bed melter – gasifier (see Table 36).

Processes which only modify the blast furnace technique such as the oxygen – coal blast furnace of BSC and NKK or the plasmaheated blast furnace Pirogas [183] are not discussed here.

In the case of processes using fine ore generally only the reduction reactor is developed. The integration of the fine-ore reduction into the process and therefore directly into the smelting reactor has not yet been realized in any of the existing pilot plants.

2.7.2.1. Processes Using Electrical Energy

These processes were developed in Sweden and consist of a prereduction stage of the fine ore and a final reduction which use electrical energy. The electrical energy is introduced via plasma burners (Plasmasmelt), electric arc (Elred), or electric resistance heating (Inred). The only process which has a technical application is the Plasmasmelt process in a modified form (Plasmadust and Plasmachrome). Because of the high electricity consumption these processes can only be consid-

ered for iron production in countries with cheap electricity.

The *Plasmasmelt process* [203, 208] was developed by SKF Steel Engineering AB. The flow sheet is shown in Figure 129. Fine ore is prereduced with a reduction gas generated in the smelting reduction stage. The prereduced material (reduction degree 50 – 60 %) is injected together with powdered coal into a coke-filled shaft furnace (melter) provided with plasma generators. Recycled process gas is used as injection gas. The final reduction and melting occur inside the coke column which also protects the refractory. A proportion of the spent reduction off-gases is combusted to dry and preheat the ore fines.

The Plasmasmelt process requires a low coke intake (consumption 50 – 100 kg /t hot metal), 1100 kWh of electricity and 200 kg coal per ton hot metal. The prereduction stage was developed separately in a 1 t/h pilot plant. Integrated operation of melting and reduction has not yet been tested.

A melter with a capacity of 8 t/h is integrated in a modified process (Plasma dust) where waste oxides from steelworks are processed in Southern Sweden.

The *Inred process* [206, 207] was developed by Boliden and tested from 1982 – 1984 in a pilot plant with a capacity of 8 t/h. Fine ore, coal, and fluxes are fed together with oxygen in a *flash-melting chamber* giving temperatures of 1900 °C. Superheated liquid FeO together with some coal char fall into the *electric furnace with submerged arc,* where final reduction takes place (see Fig. 130). Because of the high FeO content in the slag (7 – 8 %) a sulfur content of 0.15 – 0.2 % must be expected for a commercial plant.

In the *Elred process* [204, 205] fine ore is prereduced to 60 – 70 % in a single-stage fast-fluidized bed at 950 – 1000 °C before being melted down in an electric arc furnace (hollow Söderberg electrode). The reducing gas is produced by partial combustion of coal with air within the fluidized bed. The *prereduction pilot plant* was built by Lurgi with a capacity of 500 kg/h and the *electric arc furnace* by ASEA (capacity 8 t/h) (see Fig. 131). Up to now this process has found no technical application for iron production.

Figure 131. The Elred process

The *Combismelt process* combines the Lurgi prereduction rotary kiln and a submerged electric arc furnace (DEMAG). The electric energy is generated by waste heat and off-gas (see also Section 2.6).

2.7.2.2. Coal – Coke-Bed Melter – Gasifiers

In these processes the melting stage is a fixed bed or fluidized bed of charcoal or coke. Prere-

Figure 132. The Corex process, basic flow sheet with export gas
a) Melter – gasifier; b) Reduction shaft furnace; c) Coal feed system; d) Hot dust cyclone; e) Cooling-gas scrubber; f) Top-gas scrubber

duction is performed in a shaft furnace (Corex, Sumitomo) or fluidized bed (Kawasaki).

The *Corex Process* (formerly called KR process) is the most advanced smelting reduction process [186 – 189]. This process was developed by Deutsche Voest-Alpine Industrieanlagenbau (formerly Korf Engineering) and its parent company Voest-Alpine Industrieanlagenbau (VAI) in Austria to a 60 000 t/a pilot plant from 1981 to 1987 in Kehl, Germany.

The Corex process (Fig. 132) separates the iron-ore reduction and melting steps into two reactors:

1) Generation of reducing gas and liberation of energy from coal for melting occur in the *melter – gasifier.*
2) Reduction of iron ore occurs in a *shaft furnace.*

The Corex process is designed to operate under elevated pressure, up to 0.5 MPa.

Coal is fed into the gasifier (a) where it comes into contact with a reducing gas atmosphere at a temperature of ca. 1000 – 1100 °C. Instantaneous drying and degasification of the coal particles occur in this upper portion of the melter – gasifier. Reducing gas is generated in a fluidized bed, by the partial oxidation of coal. At first carbon is oxidized to carbon dioxide. Then, carbon dioxide reacts with free carbon to form carbon monoxide. The gas temperature in the fluidized bed is in the range of 1600 – 1700 °C. The temperature conditions in the freeboard zone above the fluidized bed guarantee production of a high-quality reducing gas which contains ca. 65 – 70 % carbon monoxide, 20 – 25 % hydrogen, and 2 – 4 % carbon dioxide. The remaining constituents are methane, nitrogen and steam.

After leaving the melter – gasifier, the hot gas is mixed with cooling gas to obtain a temperature suitable for direct reduction, ca. 850 – 900 °C. The gas is then cleaned in hot cyclones (d) and fed to the shaft furnace as reducing gas. A small amount of the cleaned gas is converted to cooling gas in a gas cooler. The fines captured in the hot cyclone are reinjected into the melter – gasifier.

The reducing gas is fed into the reduction furnace and countercurrently ascends through the iron burden.

The iron ore, charged into the shaft furnace through a lock hopper system, descends by gravity. The reduction reaction in the shaft furnace,

Figure 133. Expected material flow sheet for a Sumitomo SC commercial plant (F.C. = fixed carbon; V.M. = volatile matter)

using gas with ca. 70 % carbon monoxide and 25 % hydrogen is exothermic, leading to temperatures in the burden which are above the reducing gas temperature. Because of carbon monoxide decomposition, carbon deposits will form on the iron and act as a lubricant. Formation of Fe_3C occurs as well and cluster formation is avoided. The top gas is cleaned and cooled in a scrubber, and is then available for various purposes. Metallization of the DRI averages 90 – 95 %, and its carbon content is in the range of 3 – 5 %, depending on the raw material used and operating conditions.

The continuous transfer of the hot DRI (temperature 800 – 900 °C) from the reduction furnace to the melter – gasifier is carried out by a special controllable transport system which discharges into connected downcomers. The velocity of the descending sponge iron particles is lowered in the fluidized bed, further reduction is completed, heating and melting occurs. Hot metal and slag drop to the bottom of the melter –gasifier. Analogous to the practice in the blast furnace hot metal and slag are discharged by conventional tapping procedures. Tapping is carried out every 2.5 – 3 h on an average. For a good desulfurization a slag basicity >1 is required.

Temperature and silica content of the hot metal can be adjusted by various process parameters, i.e., coal particle size, height of the fluidized bed, system pressure, and rate of hot metal production.

The melter – gasifier may generate a certain amount of surplus gas depending on the coal selected. This surplus gas becomes part of the cooling gas stream, and can be either used separately or mixed with the top gas from the shaft furnace. When using a high volatile bituminous coal, the resulting gas mixture (export gas) approximates 1800 m^3 (STP)/t hot metal with a lower heating value of ca. 8000 kJ/m^3 (STP).

According to the composition and quality of the coal, the specific oxygen consumption is ca. 450 – 550 m^3 (STP)/t hot metal. The energy for the oxygen production can be supplied from about one third of the export gas of the Corex plant. The coal consumption depends on the coal quality and is ca. 0.5 – 0.7 t fixed carbon per ton hot metal.

If the export gas cannot be used economically, it is converted to reducing gas by removal of carbon dioxide and recycled. This process route offers the advantage of a lower coal and oxygen consumption.

The *Sumitomo SC process* [190, 191] uses a combination of two shaft furnaces (Fig. 133), the reduction furnace which produces DRI from lump ore and a *coke-bed melting furnace* which generates the reducing gas. Oxygen, air, and pulverized coal are blown into the coke bed. Low-grade coke is charged at the top of the melting furnace which corresponds to the lower part of a blast furnace or a cupola.

The gas coming out of the melting furnace with a temperature of 600 °C is cleaned in a cyclone, then it must be heated up by partial combustion with air to the reducing temperature of 800 °C.

Figure 134. The Kawasaki XR process
a) Fluidized bed prereduction furnace; b) Coke-bed melter; c) Upper tuyere; d) Lower tuyere

The *melting furnace* was developed in a pilot plant with a capacity of 8 t/d in 1982. In 1984 the *reduction furnace* was integrated. Expected consumption figures (see Fig. 133) for a commercial plant are given on the basis of the result obtained by the pilot plant. The expected coke consumption of 218 kg/t hot metal (in the pilot plant much higher) is nearly as high as that of a modern blast furnace with a high coal-injection rate. So the goal of a cokeless process is not achieved.

Kawasaki developed a smelting reduction process for ferrochrome production on the basis of a *coke-bed melter* with two-stage tuyeres, the *XR process* [192, 193]. Powdered ore was prereduced in a fluidized-bed reactor and injected into the furnace through the upper tuyere. For iron production, this process was modified to feed coal from the top as schematically shown in Figure 134.

Small-size degassed coal forms a fluidized bed in the upper part of the furnace and the lumpy char forms a packed bed in the lower part. The pilot plant for the XR process with a capacity of 10 t/d was started in 1987. It is planned to reduce the fines in a circulating fluidized bed to a reduction degree of 80 %.

2.7.2.3. Converter-Type Iron Bath Reactors

The converter-type melters (see Table 37) are under development from the experience of the oxygen LD-BOF converter for steelmaking (→ Steel, Chap. 3.3.1.1). Coal is injected with or without oxygen in a liquid iron bath.

In most of the processes the carbon monoxide – hydrogen gas mixture coming out of the melt is partially combusted (post-combusted) to generate heat (up to 1900 °C) which is transferred to the bath. Processes using fine ore prereduce the ore in fluidized beds to a reduction degree of 15 – 90 %. In most cases the process pressure is low (ca. 50 kPa). At present only the melting stage is developed for most of the processes. *Integrated operation* of melting and reduction has not been tested. Apart from the latter the most critical areas of these processes are refractory lifetime, gas-handling system (accretions), and foaming and splashing of the melt. Because of the high FeO-content in the slag the sulfur content of the hot metal is higher and the silicon content lower than in the blast furnace process.

Processes with Post-combustion. The most advanced converter process has been developed

by Klöckner, Germany, and CRA, Australia, since 1981 [194 – 196]. After pretests a pilot 10 t-converter started operation in 1984 with a capacity of 4 t/h where especially post-combustion was investigated. The prereduction stage was not tested in this plant. In 1987 Klöckner was bought out and CRA formed a joint venture with Midrex to further develop the process under the name *HIsmelt.* The flow-sheet of the HIsmelt process in its first stage of development is shown in Figure 135. Coal is injected from the bottom into the melt. The energy for melting and final reduction is generated by partial combustion of the converter gas with preheated air. The converter off-gas is used for prereduction of the fine ore. Because of the high oxidation degree of the gas it is only possible to reduce the ore to iron(II) oxide which is separated in a cyclone and fed to the converter. The main problem of this process is whether the high post-combustion degrees, up to 65 % depending on coal quality, and reduction degree can be maintained for continuous operation and whether the huge amount of hot gas can be handled.

Figure 135. Flowsheet of HIsmelt process for the case 47 % post-combustion and reduction to FeO
a) Air preheaters; b) Cyclone; c) Prereducer; d) HIsmelt converter

The NKK process [198, 199] is another converter type process which also operates with a high post-combustion degree (see Fig. 136). Coal and oxygen are blown in from the top to the bath. The fine ore is prereduced only to a low degree.

Figure 136. The NKK's smelting reduction process for iron-making
a) Smelting reduction furnace; b) Preheating and prereduction furnace

Since 1986 tests have been performed in a 5 t-converter. In 1988 a prereduction stage was integrated in the pilot plant with a capacity of 100 t/d.

Processes without Post-combustion. The *Coin process* [201 – 203] developed by Krupp operates without post-combustion and with a high reduction degree. In the first published flow sheets the prereduction stage was a shaft furnace. The latest one (see Fig. 137) shows a *multistage prereduction* of fine ore which was tested separately in a pilot plant. The prereduction stage is a combination of entrained-bed and fluidized-bed reactors.

The converter pilot plant was a 3 t-converter. To achieve a high degree of metallization a high reduction temperature is needed. Sticking of the ore is prevented by carbon monoxide decomposition in a prereduction stage at 500 – 600 °C. Oxygen and degassed coal is blown into the bath from the bottom. As no post-combustion delivers energy, the coal (especially high volatile coal) must be preheated and charred by inject-

ing in the converter off-gas and recycling via a cyclone. The process is very complex and integration of the multistage prereduction, the coal devolatilizer, and the converter is not easy.

2.7.3. State of the Art of Process Developments

The current situation of smelting reduction processes is characterized by further developments of melter – gasifier and iron bath reactors. Furthermore, a new third group of processes is emerging: the combination of rotary hearth furnace (RHF) and submerged arc furnace (SAF). In 1999 only the Corex process and a first RHF/SAF process are in industrial operation.

2.7.3.1. Melter – Gasifiers

The *Corex Process* (see Fig. 132) – after producing hot metal in the first operational C-1000 plant in Pretoria from 1988 to 1998 – is now operating in four industrial C-2000 plants, producing 2000 t/d hot metal per plant [219].

The Corex plant of POSCO (Korea) in Pohang started production in 1995. A hot metal production of 95 t/h and consumption figures for coal of 995 kg/t hot metal, for oxygen of 527 m^3/t hot metal as well as an availability of 94 % are achieved as representative average values.

The first hot metal of modul no. 1 of the two Jindal Corex plants at Jindal Vijayanagar Steel (India) was tapped in October 1998. The hot metal is refined in a basic oxygen furnace (BOF) steelmaking shop.

The Corex plant of Saldanha Steel (South Africa) started production in 1999. The production is based on 100 % lump ore charge; the annual capacity is 650 000 t. The hot metal is charged together with DRI into a Conarc furnace which combines the possibilities of a converter (BOF) with those of a electric arc furnace (EAF).

An economical necessity of the Corex plant operation is the utilization of the surplus gas to get a financial credit in respect of the production costs. The export gas of the Saldanha plant feeds a Midrex direct reduction plant with a production capacity of 800 000 t/a of DRI. In the case of the Jindal Corex plants the export gas is used

Figure 138. Concept of the Finex process compared to Corex

for power generation as well as for the energy supply of a pelletizing plant.

Further developments of the Corex process have been started by POSCO and VAI since 1992, aiming at the direct use of fine ores.

Fines injection into the Corex process is an important feature of a waste-free integrated plant concept without a sintering plant. Operational results are available for fine ore injection of about 5 % which has not negatively affected the Corex operation [220]. Further tests are directed to a fine ore addition of 20 to 30 %. Not only utilization of purchased fine ores and fines separated from the Corex plant, but also the recycling of iron-containing fines from steel works is considered.

The *Finex* development [221] will allow the use of 100 % fine ore charge. A three-stage fluidized-bed reactor is combined with the melter – gasifier (see Fig. 138). Fine ore is preheated (R3), prereduced to 20 to 50 % (R2), and then reduced to about 90 % (R1) before being charged into the melter – gasifier in hot condition. A Finex pilot plant for a daily production of 150 t was commissioned in 1999; this pilot plant is connected directly to the existing Corex C-2000 plant of POSCO. So a part of the reducing gas generated in the melter – gasifier can supply the fluidized-bed system of the Finex pilot plant. Test campaigns are scheduled to be performed until end of 2000 in order to acquire the operational and engineering data for commercialization [222].

2.7.3.2. Iron Bath Reactors

From the iron bath reactors mentioned in Section 2.7.2.3 only the HIsmelt and the NKK process (now DIOS process) have been further developed; in addition new processes have emerged. For all processes mentioned a commercial status has not been reached yet.

Figure 139. New HIsmelt vertical reaction vessel

HIsmelt. In 1997 Rio Tinto became the parent Company of HIsmelt Corp., Kwinana (Australia). The HIsmelt process was changed from

Figure 140. Lay-out of an industrial HIsmelt plant (8 m diameter vertical smelting reduction vessel)

a drum-like horizontal reactor to a vertical vessel (see Fig. 139), which was commissioned in 1997. Fourteen test campaigns have been conducted, involving direct injection of fine ore, steel plant reverts, and coal into the metal bath of the vertical water cooled smelting reduction vessel with 2.7 m inner diameter. Preheated air at 1200 °C, enriched with oxygen (27 or 30 % O_2), is injected through a water-cooled lance for post-combustion of CO and H_2 coming from the bath. The turbulent nature of the process is very effective at transferring this energy back to the metal bath. The off-gas is used to fire the stoves which preheat the hot air blast [223, 224]. Between August 1997 and April 1999 the plant was operated for 128 days with the longest continuous run being a 38 days campaign. With a degree of post-combustion of 60 to 80 % and cold iron

ore fines as ferrous feed, coal rates of around 880 kg/t hot metal have been recorded. Refractory wear rates less than 1 kg/t hot metal have been achieved. Next step is a scale-up to a 6 m diameter smelter for the production of 500 000 t/a. In Figure 140 a plant lay-out for producing 1.4×10^6 t hot metal per year is given, including fine ore charging, prereduction in a circulating fluidized bed and smelting in a 8 m diameter vessel.

DIOS. The NKK process (see Fig. 136) was the basis of the Japanese joint research program DIOS (Direct Iron Ore Smelting Reduction), which was promoted by the Japan Iron & Steel Federation in collaboration with the Center for Coal Utilization from 1988 to 1997. The pilot plant at Keihin Works of NKK had a 500 t/d nominal capacity. Test campaigns with this pilot plant were carried out from 1993 to 1996. The process flow sheet of the DIOS plant is illustrated in Figure 141. The plant consisted of an in-bath smelting reduction vessel and two bubbling fluidized-bed type preheating and prereduction furnaces. The smelting vessel was equipped with an oxygen blowing lance and several bottom tuyeres for bath stirring [225]. Water cooled panels at the vessel enable a high degree of post-combustion in the foaming slag. A minimum coal consumption of 780 kg/t hot metal was achieved for a low volatility coal and of 980 kg/t for a high volatility coal, with prereduction degrees of about 25 % at 750 °C and an oxygen consumption of about 750 m^3/t hot metal. The results were used to perform a feasibility study and the conceptual design of a commercial plant for a production of 6000 t/d. However, it is expected that the situation in Japan with high-performance hot metal production in blast furnaces will not allow commercializing a DIOS plant before 2010. Therefore the activities focus on the commercialization abroad to maintain the technologies in the meantime.

CCF. The cyclone converter furnace (CCF) process is characterized by melting and prereduction of fine ore in a cyclone on top of a converter-type reactor. The prereduced liquid iron oxide drips into the carbon-containing melt, where final reduction takes place. The emerging CO is post-combusted with oxygen, partly in the converter and partly in the cyclone. The CCF process was initially a development project of the European steel producers Hoogovens, British Steel, and Ilva, sponsored by the European Coal and Steel Community (ECSC). Later two different developments were undertaken by CSM, the Italian Steel Research Center in Rome, and by Hoogovens (Netherlands). In the middle of the 1990s CSM performed some trials with a small pilot plant (5 t/h) in Taranto; the process was then named *CleanSmelt*.

Figure 141. Process flow sheet of the DIOS pilot plant
CY= Cylone; PRF = Prereduction furnace; SRF = Smelting reduction vessel

Hoogovens performed tests with the cyclone part of the CCF process (20 t/h) [226] and took over the know-how of a former direct smelting project in a converter-type vessel of the "Direct Steelmaking Program" undertaken in a collaborative research by the American Iron and Steel Institute and the Department of Energy (AISI/DOE) in the USA [227]. The CCF process scheme is illustrated in Figure 142 [228]. The consumption figures calculated for producing 1 t of hot metal are given as follows: 1540 kg fine ore, 750 kg coal, 200 kg limestone and 720 m^3 oxygen. Hoogovens performed a feasibility

study for building a demonstration plant with a capacity of 700 000 t/a, until now no decision has been made for the investment.

Figure 142. CCF process scheme

AusIron. In 1981 the Ausmelt Ltd. was formed in Australia to develop and market the technology of CSIRO and of the Siromelt process (→ Copper, Chap. 5.6). The Ausmelt technology is applied to commercial production of nonferrous metals. The Ausmelt *AusIron* technology includes a bath smelting system, which has been developed by pilot tests since the beginning of the 1990s. The heart of the technology is a top submerged lance which supplies fine coal, air, and oxygen to a slag bath reactor where iron oxide is reduced. The smelting of iron bearing titania residues has been performed at Ausmelt's Melbourne pilot facility [229].

Romelt. The Romelt process was developed by the Moscow Institute of Steel and Alloys in Russia in the late 1970s. It is a single stage smelting reduction process producing liquid iron by reducing ferrous materials without preparation. A pilot plant (0.3×10^6 t/a) has operated intermittently at the Novolipetsk Iron and Steel Works since 1985, licensees for the process are Nippon Steel Corp. (Japan), Kaiser Intern. (USA) and SAIL-Romelt (India) [230, 231]. In the Romelt process the liquid iron is produced in a molten slag bath reactor using noncoking coal and oxygen. The process requires both post-combustion of about 70 % of the primary gases from the bath and high heat transfer efficiency. Oxygen is introduced into the rectangular reactor at two different levels through water cooled tuyeres. The lower level tuyeres, submerged to the slag, provide oxygen enriched blast for gasification of carbon and bath agitation while the upper row of tuyeres supply pure oxygen achieving a high degree of post-combustion. Metal and slag are individually discharged through opposite ends of the reactor. Calculated specific consumption figures per ton of hot metal for a commercial plant are 1.23 t of coal, 0.53 t of limestone, 800 to 900 m^3 O_2, 215 m^3 compressed air, 0.056 t fuel oil and 170 kWh electric power related to a productivity of 37 t hot metal per hour. Studies by Tata Steel are available about the economics of a commercial Romelt plant at several locations in India.

2.7.3.3. Rotary Hearth Direct Reduction – Submerged Arc Furnace Combinations

Production of high quality flat steel grades in electric arc steelmaking shops, based mainly on scrap, needs addition of some virgin iron to the EAF charge. In this context a new route to produce hot metal or pig iron is emerging: Coal-based direct reduction of green pellets on a rotary hearth furnace and subsequent melting of the hot DRI pellets in a submerged arc furnace. Compared to the Combismelt process (Section 2.7.2.1) in this new line the rotary kiln is replaced by a rotary hearth furnace which has a much more higher specific productivity. However, RHF units also have a limited capacity of only about 0.7×10^6 t/a.

The first industrial plant working since 1999 in this way is the *Iron Dynamics Process* of Steel Dynamics Inc. in Butler (IN, USA). Green pellets, i. e., pellets which are not hardened by firing, are prepared by mixing of iron ore concentrate and fine coal. The DRI from these dried green pellets produced on the RHF has a carbon level of 3.5 to 4 %. In the SAF the DRI is molten down to hot metal and slag by resistance heating with electric energy using submerged electrodes

in the liquid slag. The production capacity of the plant is 500 000 t/a [232].

Processes following this route have also been developed by other engineering companies. Mannesmann Demag/Demag Italimpianti (now SMS Demag) has presented a process based on the Inmetco rotary hearth furnace (see Fig. 143). The new process line is named *Redsmelt* [233].

Figure 143. Core elements of the Redsmelt process a) Rotary hearth furnace; b) Submerged arc furnace

The plant construction company Midrex started development of the process line *Fastmelt*, based on the Fastmet rotary hearth furnace. A further development has been started by Kobe Steel in 1997 with its *ITmk3 process* (Iron Technology Mark 3), developed together with Midrex Corp. Based again on the Fastmet rotary hearth furnace, this process aims at a complete separation of liquid metal and liquid slag during reduction [234]. The new process uses the same raw materials and reductants as Fastmelt, but the reduction mechanism and products are completely different. The reduction occurs at higher temperatures (1350 – 1500 °C) and shorter residence times than required for Fastmelt. The heating of the gangue and ash components leads to softening and subsequent initiation of the coalescence of slag droplet. Hollow iron shells are formed, followed by forming iron droplets completely separated from the slag. Iron nuggets with about 1.8 % C were produced with an iron content of 97 to 99 %. Pilot plant operation is being planned to confirm successful transfer of the experimental knowledge to the ITmk3 process. The *Sidcomet* process is a development of Sidmar (Belgium) to produce hot metal from DRI using an RHF. This process is in the demonstration stage [235]. It is based on the Comet RHF process developed by CRM and Sidmar, working with a mixture of iron ore, limestone, and fine coal. It was decided to build two production plants with a total capacity of 1.4×10^6 t/a.

2.7.3.4. Special Developments for Processing of Steelworks Dusts

Steelworks dusts contain relatively high contents of iron oxides and also nonferrous elements such as zinc and lead which could be enriched and recovered. Some of the aforementioned smelting reduction processes have been successfully tested for the recycling of steelworks dusts, for example HIsmelt, DIOS, Romelt, or the AISI/DOE direct steelmaking development in the USA.

New process developments are announced by some Japanese steel producing companies. Based on experience with its coke bed reactor (see Section 2.7.2.2) [193], Kawasaki Steel has developed a new smelting reduction process with a coke packed bed for simultaneous recovery of zinc and iron from EAF dust. A commercial plant to recover chromium and nickel with a dust treatment capacity of 230 t/d was started up in 1994 and has been successful operating since.

In a second stage the technology was applied to recycling of EAF dust. The key technologies were established through pilot plant tests with a scale of 10 t/d in 1996. The process uses two-stage tuyeres and employs direct feed of the raw material, without agglomeration. Fine raw materials are injected through the upper tuyere, heat is supplied from the lower tuyere. Thus, a high temperature and intensively reducing conditions prevail in the region between the tuyeres. The raw materials are fused immediately in a high temperature raceway. The concept of the process is illustrated in Figure 144. The coke rate was 1260 kg/t of dust. The Zn content of the recovered materials was stable above 60 % for EAF dust injected with about 27 % Zn; the contents of zinc in hot metal and slag were 0.005 and 0.1 % [236].

Figure 144. Kawasaki Steel concept of the smelting reduction process for EAF dust recycling

Daido Steel has developed a new dust and slag treatment process called *DSM* (Daido Special Method of Dust Slag Melting). In the DSM process EAF dust is melted together with reduced slag with a special burner to get oxidized slag and zinc concentrate. The oxidized slag obtained is used as road construction material; the secondary Zn concentrate is sold as raw material for Zn smelting. The process scheme is shown in Figure 145. A demonstration plant for a melting rate of 9 t/h started its operation in the Chita Plant of Daido Steel in 1996. Since 1999 100 % of the EAF dust of this plant is treated by the DSM process with a treatment quantity of 1500 t dust and 300 t reduced slag per month. The secondary dust of the DSM process contains more than 50 % zinc whereas about 2 % Zn and < 0.02 % Pb remain in the DSM slag [237].

2.7.4. Conclusions

Various attempts have been made for more than 30 years to develop a smelting reduction process that produces hot metal by direct processing of *fine ore* and *noncoking coal.* However, no process development that meets these requirements could be transferred to industrial application. The only important industrial process so far is the Corex process, reducing lumpy iron oxides in a shaft furnace in a first stage and processing the hot DRI in a melter – gasifier in a second stage to produce hot metal. The production of Corex plants reach about 800 000 t/a.

Direct fine ore processing with coal is enabled by the iron bath process developments. Some of these processes seem to be technical feasible (for example HIsmelt, DIOS, CCF), but their production costs for hot metal do not allow to finance such an investment if the costs have to be compared with those of existing high performance blast furnaces.

A new process line, tailored for electric steelmaking shops producing high-quality flat products, is emerging. These processes produce hot metal by combination of ore reduction with coal on a rotary hearth furnace with subsequent melting of the produced DRI in a submerged arc furnace (Iron Dynamics, Fastmelt, Redsmelt, Sidcomet).

Another new field of application for smelting reduction processes is the recycling and processing of iron-containing steelworks wastes.

3. Production of Pure and High-Purity Iron

Pure iron is required in large amounts in powder metallurgy and magnet technology. *High-purity* iron (definition, see page 158) is almost exclusively used in basic research. In general, the production of iron of a higher degree of purity does not start directly with oxidic ores, but with conventionally produced iron. However, special requirements with regard to

Figure 145. DSM process of Daido Steel in the Chita Plant

the limiting concentrations of certain impurities (e.g., copper) have to be met by the production method.

Production of Pure Iron. Pure iron is currently produced by four different processes:

1) Vacuum treatment of liquid steel
2) Electrolysis of aqueous electrolytes, usually using iron anodes that are produced by vacuum treatment of steel (see above)
3) Conversion of iron to iron carbonyls and subsequent dissociation of these compounds (→ Iron Compounds, Chap. 3.5)
4) Conversion of iron to iron chloride, subsequent purification and reduction with hydrogen.

Attempts were made as early as the turn of the century to recover "a material with the chemical purity and uniformity of early puddle iron" [238]. It was hoped that the superior corrosion resistance of puddle iron would again be achieved. The American Rolling Mill Comp., Middletown, Ohio (USA) was able to produce iron of high purity, known as *Armco Iron,* by using the conventional Siemens – Martin process (→ Steel). In the literature, the name Armco Iron is often synonymous with low-carbon iron that is produced pyrometallurgically and has a very low content of other accompanying substances. However, iron of this type is offered today by many producers and is made by the aftertreatment of well purified steel under vacuum conditions.

Depending on the origin of the liquid starting material, the *vacuum treatment* of liquid steel (→ Steel) used for the production of pure iron can remove (1) dissolved nitrogen and hydrogen (starting material: electrolytic iron), (2) carbon by reaction with oxygen (starting material: Siemens – Martin electrolytic steel or basic oxygen steel), and (3) occasionally even oxygen by reaction with carbon or hydrogen. The treatment also promotes separation of oxides of certain companion elements suspended in the liquid metal. These companion elements have a higher oxygen affinity than iron and were oxidized with oxygen in the preceding purification step. Companion substances such as copper, that are not oxidizable in the presence of metallic iron, cannot be removed by vacuum treatment. Therefore, the starting material used for this production process should not contain such substances.

The technically realizable pressure decrease is sufficient to remove gases dissolved in iron, such as nitrogen and hydrogen. Oxygen, however, can only be abstracted by using the following reactions:

$$[\mathrm{O}] + [\mathrm{C}] \rightarrow [\mathrm{CO}] \text{ or } [\mathrm{O}] + 2\,[\mathrm{H}] \rightarrow \{\mathrm{H_2O}\}$$

and by removing the resulting reaction products, carbon monoxide and water vapor. The purpose of vacuum treatment is usually decarburization.

Since the equilibrium constant

$$K_{\mathrm{C}} = \frac{[\mathrm{C}]\,[\mathrm{O}]}{p_{\mathrm{CO}}} \text{ (Vacher–Hamilton)}$$

at p_{CO} = 1 bar and 1620 °C is 0.0025 (see Fig. 146), the carbon content cannot be lowered below 0.05 % even at oxygen concentrations of 0.05 %. However, Figure 146 also shows that decarburization at a carbon monoxide pressure (total pressure or partial pressure) of 0.1 bar and with comparatively low oxygen concentrations leads to lower carbon contents. The influence of the temperature on K_C is comparatively small. Table 37 gives analytical values for pure iron produced by vacuum treatment.

Electrolytic iron, with a residual concentration of typical impurities shown in Table 37, can be produced with an expenditure of energy of 2 kWh/kg of iron (process of Husqvarna Vapenfabriks AB, Sweden) [241]. Low-carbon soft iron is employed as the anode material. The electrolytes used are, e.g., ammonium iron(II) oxalate, iron(II) chloride and iron(II) sulfate, with supporting electrolytes and possibly organic wetting agents, brighteners, and depolarizers as additives (→ Electrochemical and Chemical Deposition) [242]. The sole commercial application for electrolysis is in refining or coating. At present, the production of pure iron by electrolysis of an ore leachate in cells with inert anodes is not economical.

Figure 146. Equilibrium between oxygen and carbon, both dissolved in liquid iron

Electrolytically refined iron can be separated as a brittle, coherent cathode coating and marketed in pieces of ca. 10 mm in diameter. Further processing usually involves melting the iron in vacuum induction furnaces and possibly alloying. However, this iron can also be deposited on the cathodes in such a way that it breaks down to a powder when subjected to slight mechanical stress. This powder is an excellent starting material for sintered products. The special prop-

erties of the powder (such as high compressibility or high porosity at high values of breaking elongation) can easily be adjusted to definite requirements by varying the process parameters of electrolysis. The procedure for the production of electrolytic iron powder is as follows. After washing and careful grinding (with as little mechanical deformation of the powder particles as possible), the cathode deposits are annealed in a hydrogen atmosphere (reduction) to make the material ductile and to remove oxygen absorbed during the preliminary treatments. The powder is subsequently sized with sizing screens. The particle-size distribution desired for a particular purpose is obtained by mixing the required amounts of different particle fractions.

The concentrations of impurities contained in *carbonyl iron* are usually below the analytical detection limit, which of course depends on the analytical method employed (see Table 37). For production of carbonyl iron see → Iron Compounds, Chap. 3.2. Only high-purity iron contains still less impurities, which are detectable with extremely sensitive physical analytical methods.

Another large-scale process involves the use of *iron(II) chloride,* which is formed by dissolving sponge or scrap iron in hydrochloric acid. Iron(II) chloride is then purified, dried, and reduced with hydrogen at elevated temperature [243]. Hydrogen, in turn, is released during the dissolution of scrap iron and the hydrogen chloride formed during reduction is reused for dissolution. The iron obtained by using this method is almost as pure as high-purity iron.

Production of High-Purity Iron. High-purity iron is usually required in small quantities only and can be produced by *zone melting.* The starting product is either electrolytic iron or iron (protective gas is usually argon or argon – hydrogen mixtures). The zone purification process alters the ductility and the brittleness of the iron at very low temperatures as well as the oxygen solubility [244].

The *sublimation process* of Alloyd Electronics (United States) involves the chlorination of electrolytic iron, sublimation of the vaporized chloride ($FeCl_3$), and subsequent reduction of the sublimate—taken from the sublimation zone with the lowest degree of impurity—with hydrogen to give iron (analytical values are presented below) [245].

The use of chemical analyses is only conditionally suitable for a *comparison of the degrees of purity* of various types of high-purity iron because the concentrations come close to the detection limit of even the most sensitive methods. For this reason, the ratio of the specific electrical resistance ϱ at 300 K and at 4.2 K is frequently used as the criterion for purity. This ratio increases with even the slightest increase in the total amount of impurities. The degree of purity of pure and high-purity iron expressed as the ratio of the specific resistance at 300 K and at 4.2 K ($\varrho_{300}/\varrho_{402}$) is as follows [245]:

Iron produced in the Siemens – Martin furnace	
rolled	18
annealed, 300 °C	28
Vacuum treated, conventionally produced soft iron	29
Electrolytic iron, annealed	190
Electrolytic iron	
from carbonyl iron	207
from highly pure iron salt solution	240
Zone-melted iron	189
Alloyd iron	383

4. Aspects of Environmental Protection

In the recent past, the rapidly increasing environmental consciousness has led to considerably tightened environmental standards in many countries. In the Federal Republic of Germany, for instance, a limiting value for dust emissions of 150 mg/m^3 (STP) was stipulated as early as 1974 in the TA Luft for the prevention of air pollution. The amendment to the TA Luft in 1986 further reduced dust emissions in waste gases to 50 mg/m^3 (STP) [246]. This limit applies to *total* dust emissions. Lower limits have been set for *individual* components, such as heavy metals, e.g., 0.2 mg/m^3 (STP) for cadmium, mercury, and thallium; 1 mg/m^3 (STP) for arsenic, cobalt, nickel, selenium, and tellurium; and 5 mg/m^3 (STP) for antimony, lead, chromium, manganese, vanadium, and copper as well as cyanide and fluoride. Urged by stringent requirements, the steel industry has made substantial investments in environmental technology in recent years [247]. In the Federal Republic of Ger-

Figure 147. Sinter plant waste-gas dedusting
a) Sintering machine; b) Feed point; c) Igniter; d) Sinter; e) Wind boxes; f) Manifold; g) Electrostatic precipitator; h) Fan; i) Stack

many, for instance, from 1975 to 1984 ca. € 1.2×10^9 (10 % of the steel industry's resources for new investments) were spent on environmental protection. The lowering of dust emissions from 10 kg per tonne of raw steel in 1960 to the present value of 1.4 kg per tonne of crude steel serves as an example for the success of new techniques in controlling air pollution [248].

The endeavors towards pollution control are not limited to the *air pollution control,* but also include *water pollution control, reduction of noise,* and *waste management.* The division of capital expenditure between the individual areas in the Federal Republic of Germany (1975 – 1984) is as follows:

Air pollution control	67.7 %
Water pollution control	21.4 %
Noise reduction	9.5 %
Waste management	1.4 %
Total	€ 1204×10^6

It can be seen that the investment in air-pollution control represents two thirds of the total capital expenditure.

Apart from the *direct measures* taken to control pollution, the *saving* or *recovery* of *energy* also has a favorable effect on the environment because the corresponding amounts of energy can only be produced at the expense of the environment. The most important examples of these measures are (1) the reduction of the specific fuel consumption during sintering by half since the 1950s, (2) the expansion of blast-furnace top gas in turbines and its utilization for heating, (3) dry coke quenching, and (4) CO gas recovery (→ Steel).

Pollution-control techniques being currently employed in pig-iron production and in related auxiliary plants will be described with a series of examples. However, in view of the diversity of processes available, a complete survey cannot be presented here.

4.1. Air Pollution Control

Virtually all areas of ironworks make use of gas dedusting techniques. Apart from mechanical and filtering dust separators and scrubbers, electrostatic precipitators are frequently used today [249 – 251].

Sintering Plants. In the past, dust separation from off-gases in iron-ore sintering plants was carried out with cyclones. Today's demands are essentially fulfilled by three-field horizontal dry electrostatic precipitators, which are operated on the suction side of the sinter waste-gas fan. The waste-gas flow rate of a sinter belt with a reaction area of e.g., 400 m^2 is in the range of 1.8×10^6 m^3/h. As shown in Figure 147, the waste-gas dedusting in that case is achieved in two parallel electrostatic precipitators.

The electrical resistance of sinter dust, which in most cases is very high, frequently impedes electrostatic dust precipitation [252]. Increasing the humidity of the gas, by adding water either to the off-gas or to the sinter belt, can improve dust separation by *reducing the electrical resistance* of the dust. Dust emission can be reduced by 20 – 50 % of the starting values by conditioning the waste gas with sulfur trioxide [251]. In this process sulfur dioxide, obtained, e.g., by combustion of sulfur, is oxidized to sulfur trioxide and added to the waste gas in front of the electrostatic filter. A level of 10 – 30 ppm of sulfur trioxide in the waste gas is sufficient to reduce the electrical resistance of dust and thus cause the improvement in dedusting efficiency mentioned above. The required amount of sulfur trioxide is so low that only ca. 33 kg/h of sulfur

Figure 148. Sinter plant room dedusting
a) Sintering machine; b) Hot screening; c) Cooler; d) Cold screening and crushing; e) Sinter product; f) Return fines; g) Suction system; h) Electrostatic precipitator; i) Fan; j) Stack

are needed to produce e.g., 20 ppm of sulfur trioxide for the conditioning of the waste gas of a 400 m^2 sinter belt. Extra sulfur trioxide emission does not occur because it is bound to the dust by chemisorption (sulfate formation). The effect of this process depends on the basicity of the sinter feed and on the composition of the raw material.

Simple housings at feeding points, at the sinter discharge end, at screening machines and at numerous transport devices cannot effectively prevent the escape of dust into the surroundings. For this reason, *suction hoods* are installed that are connected by means of branched ducts to a central dedusting system, which is often an electrostatic precipitator. The schematic of a so-called room dedusting system of this type is presented in Figure 148. In many cases, the dust-laden off-gas from the sinter cooler is passed through the room dedusting plant, however, it may sometimes be led to a separate electrostatic precipitator.

Blast Furnace. A blast furnace with an open top is not used any longer. Dedusting systems have allowed the cleaning of top-gas to dust loading values of < 10 mg/m^3 (STP), and thus have permitted the utilization of the energy contained in this gas in turbines and for the heating of hot blast stoves. Apart from the direct protection of the environment brought about by top-gas purification compared to an open top, an indirect effect is achieved by saving energy which would have to be produced at the expense of the environment.

The top-gas leaving the blast furnace (a) is loaded with 10 – 40 g/m^3 (STP) of dust. The volumetric flow rate of a blast furnace that has, e.g., an output of 5000 t of hot metal per day is ca. 420 000 m^3/h (STP). Figure 149 shows the components of the top-gas purification plant of a blast furnace that is operated at a *slight overpressure.* The larger particles of dust are first separated in a gravity dust catcher (b), i.e., a settling chamber with flow deflection, and subsequently in a cyclone (c). Further cleaning of the blast-furnace gas occurs in a single- or multiple-stage scrubber (d) and in a wet electrostatic precipitator (e), which carries out both fine purification as well as removal of droplets. If the top-gas volumetric flow rates are very high, several purification plants are installed in parallel.

The top-gases from blast furnaces that are operated at *higher pressures* can be freed from dust to the desired degree of purity by using a pressure difference of ca. 20 kPa in high performance scrubbers without an electrostatic precipitator. Another effective method of top-gas dust separation is dry dust removal in electrostatic precipitators. It has the advantage of involving low pressure losses and consequently has a lower energy requirement for gas transport and, in addition, water and sludge treatments are no longer necessary. Dry top-gas purification represents the latest technological development.

Figure 149. Top-gas cleaning
a) Blast furnace; b) Gravity dust catcher; c) Cyclone; d) Scrubber; e) Wet electrostatic precipitator; f) Fan

In the area of raw material handling a room dedusting plant prevents dust emissions. The burden bunkers and conveyors are connected by a suction system to a bag filter or an electrostatic precipitator.

The *smoke* that arises during the tapping of the blast furnace represents a minor environmental problem as far as emission protection is concerned. However, it is a nuisance for the operating personnel and makes working conditions on the casting platforms very difficult. *Cast house dedusting* is being carried out for some years now to improve working conditions. In fact, even older blast furnaces are being equipped with dedusting systems [253, 254]. The enclosing of the skimmer, iron, and slag runners and their points of transfer with easily removable hoods having fireproof linings is characteristic for a casting house dedusting plant. The enclosed areas are connected to suction lines, which are preferably installed below the casting platform. The region of the tapping hole cannot be enclosed because it has to remain accessible to the drilling and plugging machines. In this case, smoke is usually caught with a suction hood placed near the tapping hole and then led to the precipitator. The flow diagram of the main, hot metal, and slag runners on a casting platform as well as the suction system is shown in Figure 150. The hatched parts of the diagram represent the enclosed areas. It can be seen that each suction point has a damper. When the plant is in operation, only the suction points at which smoke is to be trapped are opened. For instance, if no slag is discharged in the first phase of tapping, all the dampers on the slag runner remain closed.

In blast furnace tapping, the flow volume that has to be trapped, dedusted, and transported is 500 000 – 800 000 m^3/h. The power consumption of a casting house dedusting system can reach 0.8 MW, hence, modern plants are automatically controlled. Control dampers in the suction lines and variable-speed blowers draw off as little air as necessary. For example, a minimum amount of air is withdrawn during tapping pauses and maximum amounts at the start and termination of tapping. Bag filters or electrostatic precipitators are employed as dust collectors. The advantages of electrostatic precipitators are the substantially lower pressure loss and the fact that they can be operated during tapping pauses with minimal power input.

Dry Coke Quenching. As mentioned above, dry quenching of coke also has a positive effect on the environment, because of the fact that, in contrast to wet quenching, the waste heat of the coke is utilized and no cooling clouds are produced. The heat is removed from the coke with the help of recirculating gas and used for steam generation in a waste-heat boiler. In an ironworks in the Federal Republic of Germany, two 70 t/h dry coke quenching plants produce 36 t/h of steam each, which is then used as a fuel substitute in a neighboring power plant [255]. The fuel saved in this way contributes to environmental protection. An equivalent of > 20 MW of electrical power is produced.

Direct Reduction Plants. In direct reduction plants the waste gases leaving the furnace are freed from dust in an electrostatic precipitator, bag filter or scrubber, depending on the re-

Figure 150. Cast house dedusting

quirements in the operational areas. Electrostatic precipitators or bag filters are used for room dedusting plants.

Regarding the emissions of the dust components mentioned above, cadmium, lead, and possibly manganese can be of relevance in the making of pig iron, however, the limiting values for these metals are generally adhered to.

4.2. Prevention of Water Pollution

In the course of pig iron production, modern ironworks cause practically neither water pollution, nor warming up of waters. Only small amounts of water are required in *sintering plants* for rolling the burden and, if necessary, for sinter cooling or gas conditioning. The water used is released into the atmosphere in the gaseous state through the waste gas stack. Generally, *direct reduction plants* do not produce wastewater.

Blast furnaces, on the other hand, have a considerable water requirement for cooling. In the past, up to 60 m^3 of water were consumed per tonne of pig iron [256]. Another water-consuming process pertaining to the blast furnace is wet top-gas purification. It is becoming increasingly rare today that the wastewater of this process is released into the atmosphere. In fact, the introduction of a closed water circulation with the appropriate water conditioning plant [257, 258] for top-gas purification and blast furnace cooling contributes to the marked decrease in the water requirement for steelmaking, which is today ca. 30 m^3 per tonne of raw steel [248].

Blast-furnace cooling with a closed circulation requires water-cooling plants. Usually the circulation water is evaporated in the blast furnace coolers and condensed and cooled in cooling towers.

The essential components of a scrubber/precipitator effluent for top-gas purification are shown in Figure 151. The clarification of the effluent can be carried out in a thickener and the dewatering of the sludge in a filter press. However, other dewatering machines, such as drum or rotary disk filters may be applied.

4.3. Noise Reduction

As in other industrial plants, numerous sources of noise exist in ironworks, which contribute to the total noise emission. Many of these noise sources are not specific to the production of pig iron. These include fans, compressors, pumps and ore-dressing plants. The noise abatement measures consist of, e.g., the use of low-vibration motors, the enclosing of machines or other apparatus, or even entire parts of the plant, such as the sinter waste-gas fans [259].

Figure 151. Effluent treatment for top-gas cleaning
a) Thickener; b) Filter press; c) Cooling tower

Special measures are required to dampen the feeding and expansion noises at hot blast stoves. Considerable noise reduction can be achieved here by covering the valves and the expansion line with a sound-absorbing material and by using sound absorbers or perforated disks in the blowoff line [260]. Emission values of ca. 40 dB(A) can be achieved at a distance of 1000 m from a blast furnace or sintering plant if noise damping measures are used consistently [261].

4.4. Waste Management

Blast furnace slag is quantitatively the most important waste material created in the production of pig iron. This material is completely utilized. About two thirds of the total amount is employed in road construction. The remainder is used by the cement industry for the production of blast furnace cement [262].

The recycling of the *dry dust* obtained in top-gas purification also causes no problems because it can be recycled to the sintering plant. However, *blast furnace sludge* is for the most part still being dumped, in amounts of 130 000 t/a in Germany [263]. The reason for this is the high content of lead, zinc and alkali found in the sludge. If the sludge were recirculated, these substances would accumulate in the blast furnace. Today, various processes are available which reduce the environmental impact caused by these dumps by allowing the recycling of blast furnace sludge and other waste containing lead and zinc.

One way of expelling the unwanted accompanying substances is the reprocessing of dusts and sludge in rotary kilns [264 – 267]. The product thus obtained consists essentially of metallic iron, which can, e.g., be briquetted and returned to the pig iron production [268].

Most of the *dust* separated in the waste-gas precipitators of sintering plants can usually be led back into the process. Only the dust arising in the last field of the electrostatic precipitator must be removed from the circulation because of alkali enrichment.

The *prime goal* is always the avoidance or minimizing of residual substances. For example, the specific amount of slag has decreased from 800 kg/t at the beginning of the 1950s to 300 – 350 kg/t of pig iron today. In a modern steel plant, ca. 90 % of the total amount of waste products is recycled.

5. Economic Aspects

Hot Metal. The conventional and by far the most common approach to iron production involves reducing and smelting the iron ore in a blast furnace together with coke, the immediate product being hot metal. Hot metal, in turn, is the principal pre-product for the production of commercial crude steel. Production of a tonne of

Table 38. Hot metal production and fraction of world output, by country

in some cases estimates
IISI, Statistical Yearbook 2001, p. 96 – 97; Statistisches Jahrbuch Stahl, WV 2001, p. 378.

steel requires ca. 700 kg of hot metal in addition to scrap and flux.

World production of hot metal in 2000 reached a level of 576 $\times$ 10^6 t, iron ore production a level of ca. 1051 $\times$ 10^6 t (see Tables 38 and 39) [269]. The European Community alone produced 95.2 $\times$ 10^6 t of hot metal in 2000, using 134.5 $\times$ 10^6 t of iron ore together with 40 $\times$ 10^6 t of coke (blast furnace coke plus sinter coke breeze). The major cost factors in hot metal production are related to raw materials (49 %), reductants (30 %), and processing (21 %) [270].

In view of the massive requirements for raw material and energy, and investment costs, the potential for savings through optimization of scale and exploitation of more economical

Figure 152. Evolution of blast furnace burden composition (A) and reductant rate (B) in the Federal Republic of Germany since 1950 for basic hot metal

sources of raw material is extremely attractive. Environmental protection measures have also come to play an increasingly important economic role in hot metal production in recent years.

Careful organization and quality control on the input side of hot metal production is also important with respect to the properties of the principal end product – steel – and consequently on the market picture as it relates to steel vs. alternative materials. Economic factors and quality are therefore closely linked.

Several recent developments deserve special mention as determinants of the competitiveness of steel, especially from the standpoint of cost reduction:

1) Increased emphasis on major sources of ore displaying a high iron content, a consideration which helps to minimize fluctuations in ore quality.
2) Significant improvement in the facilities for *handling* and *transporting* ore in increasingly large unit amounts. Intercontinental marine ore transport today involves units as large as 350 000 dwt (i.e., dead weight), representing a three-fold increase in maximum load in the course of 30 years.
3) Steady improvement in the *preparation of the furnace charge* in terms of ore classification, sintering, and pelletizing. For example, the use of lump ore has decreased in the Federal Republic of Germany from 35 % in 1970 to 10 % ca. 2000. Sinter input, on the other hand, has increased to 60 %, and pelletized ore – virtually unknown before 1965 – now represents 30 % of the charge (see Fig. 152).
4) Significant decrease in *reductant consumption* and more variety in the nature of the injected reductants employed for reduction.

Reducing agent consumption has dropped by a total of ca. 20 % over the last 30 years, now amounting to only 475 kg per tonne of hot metal. Coke continues to constitute the major source of reductant (360 kg/t), although since about 1986 inexpensive coal has increasingly been used as a coke substitute (81 kg/t HM as average in Germany). Oil injection currently accounts for ca. 33 kg/t HM.

By far the largest part of the hot metal output goes into *steel production*.

In Europe essentially *no open market* exists for basic hot metal, because the steel industry is effectively self-supporting. Iron of this type is purchased only rarely and in times of shortage, as when demand is particularly strong or some industrial mishap causes supply problems. By contrast, there is a lively trade in such products as *foundry iron, hematite iron,* and *spheroidal pig iron*.

Amtliche Außenhandelsstatistik

The largest exporter of pig iron, and by a wide margin, are *Russia* and *Brazil* at 3.6 to 3.8 $\times$ 10^6 t/a (see Table 40) [271].

DRI (Direct Reduced Iron). The direct reduction process (see Section 2.6) provides the market with another form of reduced iron: DRI, available in significant quantity since the 1970s

and produced from lump ore or pellets, mainly with gas as reductant. The current world output of DRI is 43×10^6 t/a (see Table 41, [272]).

This production method represents a significantly different route to hot metal production when natural gas is available in abundance and for a low price as in the case of Indonesia, Malaysia, the Middle East, Mexico, and Venezuela. Indeed, DRI can often be produced for \$ 120/t under appropriate conditions, and most of the direct reduction facilities currently in operation are located in the regions cited [273].

DRI is devoid of elemental silicon and phosphorus, and it contains only little carbon – i.e., it lacks any source of energy for the subsequent conversion to steel. In this sense it is comparable to steel scrap, and it is highly priced as a charge for electric furnaces where these can be operated economically.

Alternative Production Methods. So far, no other alternative routes to produce liquid hot metal than the Corex process have achieved any significance. The Corex method utilizes a direct reduction shaft and a melter – gasifier (see Section 2.7) which was developed in Germany and first introduced in South Africa in 1988. In 2001 in total four units operated in India, South Africa and South Korea. One important advantage of the process is that the expensive construction of coking and sintering facilities can be avoided. The Corex process is dependent on lumpy ferrous burden materials (lump ores and/or pellets).

Size of the Production Facility. One way of classifying the various manufacturing methods is in terms of dimension (scale, capacity). For example, *blast furnaces* today may be as large as 14.9 m in diameter, with a working volume of 4789 m^3 (Schwelgen no. 2, Thyssen Krupp Stahl). Yearly the hot metal production reaches over 4×10^6 t. Local and company factors may well dictate smaller units.

For technical reasons, *direct reduction* facilities are much smaller, with a typical maximum annual output of 1.3×10^6 t DRI/modul. The *smelting reduction* Corex units are currently producing 0.6 to 0.8×10^6 t hot metal per annum. The economy of a Corex unit is linked with gas credits for the export gas produced at higher quantities.

Lower investment costs are responsible for the fact that smaller steel mills in particular (i.e., those with an annual output $< 1 \times 10^6$ t) tend to utilize a direct-reduction or smelting-reduction iron process in contrast to the blast furnaces at larger integrated steel mills, where the *lower reductant consumption* associated with a conventional blast furnace is the decisive factor [274].

The principal economic factors addressed here with respect to iron intended as a precursor to steel – performance of the production unit, investment costs, energy consumption, advantages of scale – all suggest that the blast furnace will continue to retain its primacy over the long term. Only where unusual local conditions favor other sources (through cheap sources of energy or limited demand) is the otherwise efficient and economical blast furnace likely to be displaced.

1. Iron Sulfates

1.1. Iron(II) Sulfate

Properties. Iron(II) sulfate heptahydrate [*7782-63-0*], ferrous sulfate, copperas, green vitriol, $FeSO_4 \cdot 7\,H_2O$, M_r 278.02, *mp* 64 °C, ϱ 1.898 g/cm^3, crystallizes from aqueous solution as green, monoclinic crystals, which are readily soluble in water and glycol but insoluble in alcohol, acetone, and methyl acetate. On being heated to 60 – 70 °C, 3 mol of water is driven off to form the tetrahydrate [*20908-72-9*], $FeSO_4 \cdot 4\,H_2O$. In the absence of air, at ca. 300 °C, iron(II) sulfate monohydrate, a white powder, is formed. When heated to ca. 260 °C in the presence of air, the monohydrate is oxidized to iron(III) sulfate. Decomposition of iron(II) sulfate begins at about 480 °C. Iron(II) sulfate is efflorescent in dry air. In moist air, the surface of the crystals becomes covered with brownish basic iron(III) sulfate. Aqueous solutions of iron(II) sulfate are slightly acidic due to hydrolysis. The rate of oxidation by air increases in alkaline solution and on raising the temperature. Iron(II) sulfate reduces copper(II) ions to copper(I) ions and gold or silver ions to the corresponding metal. With univalent cations (e.g., K, Rb, Cs, NH_4, and Tl) and divalent cations (e.g., Cd, Zn, Mn, and Mg), double salts (alums) are readily formed; an example is Mohr's salt, iron(II) ammonium sulfate, $FeSO_4(NH_4)SO_4 \cdot 6\,H_2O$. This green salt is soluble in water, easily purified, and more stable to oxidation than iron(II) sulfate heptahydrate.

Production. Iron(II) sulfate is produced by dissolving scrap iron in dilute sulfuric acid or by oxidizing moist pyrites in air.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a14_591

Iron(II) sulfate is also obtained as a byproduct from steel pickling (see Chap. 6) and from the production of titanium dioxide (sulfate process, with ilmenite as raw material). It is recovered from pickling liquors in a relatively pure form. The purity of iron(II) sulfate from the production of titanium dioxide depends on the source of the ilmenite. A typical composition is 87 – 90 % $FeSO_4 \cdot 7\,H_2O$, 6 – 7 % $MgSO_4 \cdot 7\,H_2O$, 0.6 – 0.7 % $TiOSO_4$, 0.2 % $MnSO_4 \cdot 7\,H_2O$, 3 – 6 % water, and depending upon the type of ilmenite used, traces of nickel, chromium(III), vanadium, copper, zirconium, and others.

Uses. Iron(II) sulfate is used for the preparation of other iron compounds. It is employed to a lesser extent in writing inks, wood preservatives, desulfurizing coal gas, and the production of Turnbull's blue, Prussian blue, and other iron pigments; as an etchant for aluminum; for process engraving and lithography; and as an additive to fodder.

As sensitivity to environmental protection increased, other uses had to be found for iron(II) sulfate, because the above mentioned applications did not consume the amounts available as a byproduct from industrial processes. Large amounts of iron(II) sulfate are used for the clarification of community effluents. With an additional clarification step, up to 90 % of the phosphate in the effluent can be eliminated. Sludge formed in clarification tanks may be used as fertilizer [1], [2]. Iron(II)sulfate can also be recycled. After drying to the monohydrate, it is decomposed in a calciner:

$$4\,FeSO_4 \longrightarrow 2\,Fe_2O_3 + 4\,SO_2 + O_2$$

Sulfur dioxide is converted by the contact process to sulfuric acid [3]. The conversion of iron(II) sulfate to gypsum and iron(II) chloride by treatment with calcium chloride has also been proposed. The iron(II) chloride is then decomposed to iron(III) oxide and hydrochloric acid [4]. To convert surplus iron(II) sulfate to a product that can be disposed on a dump site, it can be neutralized with one equivalent of calcium hydroxide. The conversion is reportedly 97 % [5]. To regulate the setting characteristics of cement, gypsum can be replaced by iron(II) sulfate [6]. As an additive to cement, iron(II) sulfate can reduce the content of water-soluble chromates substantially [7]. Iron(II) sulfate solutions can be used to eliminate chlorine in waste gases [8]. Effluents containing cyanides and chromates may be decontaminated with iron(II) sulfate [9]. Iron(II) sulfate can be used to combat chlorosis, a disease of vines [6]. It is also used to treat alkaline soil and to destroy moss [6].

Toxicology. If swallowed, iron(II) sulfate can cause disturbances of the gastrointestinal tract. Ingestion of large quantities by children may cause vomiting, hematemesis, hepatic damage, and peripheral vascular collapse [10].

The acute oral toxicity (LD_{50}) of iron(II) sulfate in the rat is 1389 – 2778 mg/kg, and the in rabbit, 2778 mg/kg [11].

1.2. Iron(III) Sulfate

Properties. Anhydrous iron(III) sulfate [*10028-22-5*], ferric sulfate, $Fe_2(SO_4)_3$, M_r 399.88, is a yellowish-white solid. It dissolves in water, hydrolyzing at the same time, to yield a brownish solution. Basic iron(III) sulfate precipitates when the solution is boiled. With alkali metal (M) sulfates, iron(III) sulfate forms alums, $M^I Fe(SO_4)_2 \cdot 12\,H_2O$. Alums are almost colorless but normally have a violet tinge.

Production. Iron(III) sulfate is prepared by treating iron(II) sulfate with boiling concentrated sulfuric acid, or by evaporating a mixture of iron(III) oxide and sulfuric acid. Iron(III) sulfate solutions are produced industrially by injecting chlorine gas into an iron(II) sulfate solution [12]. The solution thus obtained contains a mixture of iron(III) sulfate and iron(III) chloride.

Uses. Ferric sulfate is used to prepare alums and iron oxide pigments, and as a coagulant for the treatment of liquid effluents. Ammonium ferric sulfate is used for tanning.

Solutions of iron(III) compounds are used to reduce the volume of sludge from effluent treatment plants. By using a mixture of iron(III) sulfate, iron(III) chloride, and calcium hydroxide it is possible to achieve a dry-matter content of the sludge, after filtration, of at least 35 % [13].

2. Iron Chlorides

Of the halides of iron, only iron(II) chloride and iron(III) chloride have become important commercially.

2.1. Iron(III) Chloride

Iron(III) chloride [*7705-08-0*], ferric chloride, is a byproduct of some metallurgical and chemical processes, such as the chlorinating decomposition of iron-bearing oxide ores. Its ready availability and the cheap feeds used to produce it (iron and chlorine) have made iron(III) chloride, especially its aqueous solution, a significant feed stock for many industries, in particular, water treatment and the production of iron oxides or other iron compounds.

Properties. Iron(III) chloride, $FeCl_3$, M_r 162.206, sublimation temperature ca. 305 °C, *bp* 332 °C [14], ΔH_f^0 (25 °C) – 399.67 kJ/mol [14], ϱ (25 °C) 2.89 g/cm^3 [15], is an almost black crystalline solid.

It is dimeric (Fe_2Cl_6) in the gas phase up to about 400 °C, dissociates at higher temperature, and is monomeric at 750 °C in the presence of excess chlorine. If chlorine is not present in excess, the compound decomposes to iron(II) chloride and chlorine above 200 °C [16].

Anhydrous iron(III) chloride has a hexagonal layer structure and forms dark, almost black, microcrystalline platelets with a metallic luster. The strongly hygroscopic crystals form a series of hydrates in humid air ($FeCl_3 \cdot x\,H_2O$, $x = 6$, 3.5, 2.5, 2) [17] and deliquesce on absorbing more moisture. The crystalline commercial product is iron(III) chloride hexahydrate [*10025-77-1*], $FeCl_3 \cdot 6\,H_2O$, M_r 270.30, *mp* ca. 37 °C. It forms yellow crystals and occurs as $[FeCl_2(H_2O)_4]^+Cl^- \cdot 2\,H_2O$.

Iron(III) chloride is very soluble in water: 430 g of $FeCl_3$ per kilogram of solution at 0 °C, 480 g/kg at 20 °C, and 743 g/kg at 40 °C [18]. The enthalpy of solution of anhydrous iron(III) chloride is 95 kJ/mol for the formation of a 40 % solution at 20 °C. The aqueous solution is strongly acidic. If a solution of iron(III) chloride is diluted and neutralized slowly with alkali, $[Fe(H_2O)_6]^{3+}$ is deprotonated to give yellow $[Fe(OH)(H_2O)_5]^{2+}$ and dimeric $[Fe_2(OH)_2(H_2O)_8]^{4+}$. Brown, colloidal β-FeOOH is formed upon further neutralization; at higher temperature, iron hydroxide precipitates [19].

Iron(III) chloride is readily soluble in liquids having donor properties, such as alcohols, ketones, ethers, nitriles, amines, and liquid sulfur dioxide, but only sparingly soluble in nonpolar solvents such as benzene and hexane. The reaction of iron(III) chloride with hydrochloric acid or chlorides yields the tetrachloroferrates $[FeCl_4]^-$ and $[FeCl_4(H_2O)_2]^-$. Because complexes are also formed with donor solvents, iron(III) chloride can be extracted from aqueous solutions in the presence of hydrochloric acid by using ether [20].

Iron(III) chloride is a strong oxidizing agent. Thus, many metals (for example, Fe, Cu, Ni, Pd, Pt, Mn, Pb, and Sn) are dissolved by aqueous iron(III) chloride, with the formation of iron(II) chloride; magnesium dissolves with evolution of hydrogen. Iron(III) chloride solution liberates carbon dioxide from alkali-metal carbonates. When iron(III) chloride is heated in air, iron(III) oxide and chlorine are produced. Above 200 °C, iron(III) chloride is rapidly reduced by hydrogen to iron. It is also reduced by coal.

Production. Anhydrous iron(III) chloride is produced industrially by reaction of dry chlorine with scrap iron at 500 – 700 °C [21]. The process is known as direct chlorination. Preheated scrap is charged into the top of a water-cooled iron shaft furnace, while chlorine (or a mixture of chlorine and nitrogen) is admitted at the bottom. To prevent formation of iron(II) chloride, a 10 – 30 % excess of chlorine is used. Iron scrap is added continuously at a rate depending on the reaction temperature and the amount of chlorine remaining in the exit gas. The iron(III) chloride vapor produced passes through water- or air-cooled condensation chambers. The crystals obtained are removed continuously from the walls by vibration or knocking. They are then ground, screened, and packaged with exclusion of moisture. Chlorine in the waste gas is removed either by scrubbing with iron(II) chloride solution, to give iron(III) chloride, or by reacting with sodium hydroxide solution, to yield sodium hypochlorite and sodium chloride.

In another process, carried out in a reactor with an acid-resistant liner, iron scrap and dry

chlorine gas react in a eutectic melt of iron(III) chloride and potassium or sodium chloride (e.g., 70 % $FeCl_3$ and 30 % KCl) [22]. First, iron scrap is dissolved in the melt at 600 °C and oxidized to iron(II) chloride by iron(III) chloride. Iron(II) chloride then reacts with chlorine to yield iron(III) chloride, which sublimes and is collected in cooled condensation chambers.

The advantages of direct chlorination include higher space – time yields, lower capital cost, and less waste. The melt process gives a purer product because impurities remain largely in the melt; however, for this reason the melt must be changed and disposed of frequently.

Iron(III) chloride solutions are prepared by dissolving iron in hydrochloric acid and oxidizing the resulting iron(II) chloride with chlorine. In a continuous, closed-cycle process, iron(III) chloride solution is reduced with iron and the resulting iron(II) chloride solution is reoxidized with chlorine. Iron(III) chloride solution is also produced by dissolving iron(III) oxide in hydrochloric acid. Solid iron(III) chloride hexahydrate is crystallized by cooling a hot concentrated solution.

Quality Specifications and Analysis. Commercial forms of iron(III) chloride include sublimed anhydrous iron(III) chloride ($\geq$ 99 % $FeCl_3$), iron(III) chloride hexahydrate (ca. 60 % $FeCl_3$), and iron(III) chloride solution (ca. 40 % $FeCl_3$). Iron(III) chloride for potable water treatment must comply with DIN 19 602 (February 1987).

Trivalent iron is determined by iodometric titration with sodium thiosulfate; chloride ion is determined by argentometry.

Occupational Health. Iron(III) chloride irritates the skin and, especially, eyes. Therefore, workers handling it must wear protective glasses, facial protection, and rubber gloves. The TLV for iron(III) chloride is that for soluble iron salts: 1 mg of iron per cubic meter.

Storage and Transportation. Anhydrous iron(III) chloride can be stored in standard steel containers. It is shipped airtight in sheet-iron drums or plastic barrels, and loose in tank trucks. Moist iron(III) chloride and iron(III) chloride solutions attack ordinary metals. The following materials are suitable for containers to hold iron chloride solutions: rubberized steel; plastics such as polyethylene, poly(vinyl chloride), and polytetrafluoroethylene; fiber-reinforced plastics; glass; stoneware; porcelain; and enamel. The only suitable metallic materials are titanium, tantalum, and Hastelloy C.

The transport classification for anhydrous iron(III) chloride is UN No. 1773, RID – ADR Class 8.11 c, and for iron(III) chloride solution, UN No. 2582, RID – ADR Class 8.5 c.

Iron(III) chloride spilled by accident must be collected and forwarded to a sewage plant for disposal. Contaminated soil must be cleaned with a large amount of water and neutralized with lime. Iron(III) chloride is a Class 1 hazard to water quality.

Uses. Anhydrous iron(III) chloride is used in organic chemistry as a chlorinating agent for aliphatic hydrocarbons and for aromatic compounds. It also acts as a catalyst in Friedel – Crafts syntheses and condensation reactions. Iron(III) chloride is also used occasionally as an oxidizing agent [23], [24].

Because solutions of iron(III) chloride dissolve metals such as copper and zinc without troublesome evolution of hydrogen, they are used for the etching or surface treatment of metals (e.g., in the manufacture of electronic printed circuits, copperplate rotogravure printing, textile printing rolls), and for making signs. Iron(III) chloride solutions are also used in leaching the copper ore chalcopyrite (→ Copper, Chap. 5.10.).

Iron(III) chloride is used as a starting material in the preparation of other iron compounds, particularly oxides and hydroxides. However, most iron(III) oxide pigments obtained by hydrolysis of iron(III) chloride at high temperature have weak colors and a bluish cast, so these processes have not achieved commercial importance.

The largest use of iron chloride is in the form of dilute solutions that are employed as flocculating and precipitating agents in water treatment [25]. In processing surface waters into potable and process water, 5 – 40 g of iron(III) chloride is added to 1 m^3 of crude water at pH 6 – 7. The precipitated iron(III) hydroxide adsorbs finely divided solids and colloids (e.g., clays and humic acids). If decarbonization or the precipitation of heavy metals is to be carried out at the

same time, slaked lime is added to adjust the pH to 9 – 11.

In municipal and industrial wastewater treatment, iron(III) chloride is particularly effective because it precipitates heavy metals and sulfides, whereas contaminants such as oils and polymers, which are difficult to degrade, are adsorbed on the iron hydroxide flocs. Phosphates are also lowered to a level of ca. 1 mg of phosphorus per liter of water in the clarifier discharge. Preliminary treatment with iron(III) chloride can increase the capacity of overloaded clarifier plants.

Sludge conditioning with iron(III) chloride and lime improves the dewatering of filter sludge, so that drier sludges, better suited to disposal or incineration, are obtained.

Consumption of iron(III) chloride in the United States in 1994 was as follows [26]:

Sewage and wastewater treatment	65 %
water treatment	25 %
Catalyst, etchant, and other	10 %

Solutions of iron chlorosulfate, $FeClSO_4$, obtained by chlorinating iron(II) sulfate, are also used extensively as flocculants in water treatment [28].

Economic Aspects. Of the few anhydrous iron(III) chloride producers worldwide, the most important in Europe is BASF. Most of the iron(III) chloride is obtained as a byproduct when iron-bearing raw materials are chlorinated or when steels are pickled with hydrochloric acid (see Chap. 6); the major commercial form is the 40 % solution.

Outputs (by year, as 100 % $FeCl_3$) and major producers are

Europe (1994)	estimated 150 000 t (Solvay, Atochem, BASF, SIDRA)
USA (1994) [26]	200 000 t (Du Pont, PVS, Imperial West Chem.)
Japan (1987) [27]	322 000 t

The most important European producers of iron chlorosulfate are Kronos Titan and Thann et Mulhouse SA.

2.2. Iron(II) Chloride

Iron(II) chloride [*7758-94-3*], ferrous chloride, is much less important industrially than iron(III) chloride. The etching of steel with hydrochloric acid yields large amounts of iron(II) chloride, which is chlorinated in solution or thermally decomposed to iron oxide and hydrochloric acid. A solution of iron(II) chloride is also obtained as a byproduct from the chloride process for the production of titanium dioxide.

Properties. Iron(II) chloride, $FeCl_2$, M_r 126.753, *mp* 677 °C, *bp* 1074 °C, ΔH_f^0 (25 °C) − 342.1 kJ/mol, ϱ (25 °C) 3.16 g/cm^3, forms pale green, rhombohedral crystals which are readily soluble in water, alcohol, and acetone, but only sparingly soluble in ether and benzene. The compound occurs naturally as the mineral lawrencite. It forms several hydrates, $FeCl_2 \cdot x\,H_2O$ ($x = 1, 2, 4, 6$).

When heated in air, iron(II) chloride forms iron(III) chloride and iron oxides. Iron(II) chloride solution undergoes virtually no hydrolysis; it is oxidized readily by air.

Production. Anhydrous iron(II) chloride is produced from iron filings heated to red heat in a stream of hydrogen chloride or from iron and chlorine at 700 °C. The product is obtained as a sublimable white mass. Iron(II) chloride can also be prepared by passing hydrogen over heated iron(III) chloride.

Solutions of iron(II) chloride are prepared by dissolving iron in hydrochloric acid or by reducing iron(III) chloride solutions with iron. When a hot saturated solution is cooled to 0 °C, pale green, monoclinic crystals of the hexahydrate are obtained; cooling to room temperature yields the blue-green tetrahydrate. If the solution is concentrated at 90 °C, the green dihydrate is obtained; above 120 °C or on vacuum evaporation, the dihydrate is converted to the monohydrate, $FeCl_2 \cdot H_2O$. In the absence of air, the monohydrate is converted to anhydrous iron(II) chloride at 230 °C [29].

Quality Specifications. Iron(II) chloride is sold as an anhydrous powder (≥96 % $FeCl_2$), as the dihydrate (>75 % $FeCl_2$), as the tetrahydrate (>60 % $FeCl_2$), and as an aqueous solution (ca. 30 % $FeCl_2$).

Transportation. Solid iron(II) chloride is shipped in sheet-iron drums, plastic bags, or glass containers, and its solution is transported in rubberized containers or plastic barrels.

Uses. Iron(II) chloride is used as a reducing agent and for the production of other iron compounds. Increasingly, iron(II) chloride solution serves as a precipitating and flocculating agent with reducing properties for use in water treatment; it is especially effective with wastewater containing chromate, for example.

Pure iron(II) chloride solution is an important starting material for the preparation of acicular goethite, α-FeOOH, and lepidocrocite, γ-FeOOH, which are further processed to γ-Fe_2O_3 magnetic pigments. Pure iron(II) chloride is also employed in the preparation of pure iron.

3. Iron Pentacarbonyl

Metal carbonyls are complexes in which carbon monoxide is coordinated to the central metal atom (→ Organometallic Compounds and Homogeneous Catalysis). Of the iron carbonyls, only iron pentacarbonyl [*13463-40-6*], $Fe(CO)_5$, is economically significant.

M. Berthelot [30] and, independently, L. Mond and L. Quincke [31] discovered iron pentacarbonyl in 1891 [32]. Only after BASF had developed high-pressure technology for ammonia synthesis was its industrial production feasible. In 1925, a large plant was built in Germany by BASF to make iron pentacarbonyl, which had proved to be a very effective antiknock agent for Otto engines. When the compound was replaced shortly afterwards by lead alkyls, which were beneficial to motors, the production of iron powder from iron pentacarbonyl came to the fore.

In 1940, GAF began producing the pentacarbonyl in the United States under license from BASF. A BASF plant was moved to the former Soviet Union in 1945. Plants built in England (1944) and France (1952) have ceased production. In addition to iron powder, BASF has been producing pure iron oxide from the carbonyl since about 1930.

3.1. Properties

Physical Properties. Iron pentacarbonyl, M_r 195.9, is a clear, yellow, mobile liquid with an indistinctive odor. The molecule has a trigonal-bipyramidal structure [33].

Endothermic decomposition to iron and carbon monoxide begins at ca. 60 °C. Although decomposition becomes marked at the boiling point, iron pentacarbonyl can be distilled at atmospheric pressure with slight losses.

Some physical properties of iron pentacarbonyl are as follows:

mp	− 20 °C
bp	103 °C
Critical temperature	285 – 288 °C
Critical pressure	2.90 MPa
Heat of fusion	69.4 kJ/kg
Heat of vaporization	190 kJ/kg
Specific heat (20 °C)	1.2 kJ kg^{-1} K^{-1}
Viscosity (20 °C)	76 mPa · s
Surface tension (20 °C)	0.022 N/m
Coefficient of linear expansion (20 °C)	0.00125
Refractive index (n_D^{22})	1.518
Thermal conductivity	0.139 W m^{-1} K^{-1}
Enthalpy of dissociation (vapor)	994 kJ/kg
Heat of combustion (to CO_2 and Fe_2O_3)	− 8200 kJ/kg
Density, g/cm^3	
at 0 °C	1.495
at 20 °C	1.457
at 40 °C	1.419
at 60 °C	1.380
Vapor pressure, kPa	
at 20 °C	3.49
at 60 °C	21.33
at 100 °C	87.58

Iron pentacarbonyl is completely miscible with petroleum ether, hexane, benzene, pentanol and higher alcohols, ethyl ether, acetone, acetic acid, and ethyl acetate. It is partially miscible with paraffin oil and lower alcohols up to butanol [35].

Water solubility data for iron pentacarbonyl are contradictory; a value of 50 – 100 mg/L can be assumed [36]. The solubility of water in iron pentacarbonyl is 200 – 400 mg/kg.

The most complete documentation on iron pentacarbonyl is given in [37]; for earlier literature, see [38].

Chemical Properties. Iron pentacarbonyl is an easily combustible substance. It does not react with water or with weak or dilute acids. With

concentrated acids, the corresponding iron salts are formed with the evolution of carbon monoxide and hydrogen. Reactions with halogens yield iron halides. Iron pentacarbonyl also reduces organic compounds; for example, nitrobenzene is reduced to aniline; ketones to alcohols; and indigo to indigo white. The Hieber base reaction yields iron carbonyl hydride or its salts [41–45]:

$$Fe(CO)_5 + 4\,NaOH \longrightarrow Na_2Fe(CO)_4 + Na_2CO_3 + 2\,H_2O$$

The salt $Na_2Fe(CO)_4$ is a strong reducing agent.

Visible-light photolysis of pure iron pentacarbonyl or its solutions yields diiron nonacarbonyl, which precipitates as golden hexagonal platelets [46], [47]:

$$2\,Fe(CO)_5 \xrightarrow{h\nu} Fe_2(CO)_9 + CO$$

The trinuclear iron carbonyl $Fe_3(CO)_{12}$ is also known [48–53].

As a highly reactive and readily available compound, iron pentacarbonyl is used for the preparation of many complexes, but these are not very significant industrially [39].

The most important industrial reactions of iron pentacarbonyl are thermal decomposition in the absence of air, yielding iron powder and carbon monoxide, and combustion to iron(III) oxide, Fe_2O_3; (see Section 3.5).

3.2. Production

Although nickel carbonyl can be obtained from nickel and carbon monoxide at atmospheric pressure and moderate temperature, the production of iron pentacarbonyl requires a pressure of 5 – 30 MPa, a temperature of 150 – 200 °C, and the presence of reactive iron.

Values reported for the reaction equilibrium are not in good agreement with those calculated [54–57]. Table 1 lists experimental data for the equilibrium constant along with values calculated from the Nernst approximation [57].

Even at high temperature and pressure, massive iron reacts sluggishly with carbon monoxide, so iron sponge, with its greater surface area, is used as starting material [58]. Better yields are said to be obtained with iron quenched and granulated from the melt and containing 2 – 4 % sulfur [59], which has a catalytic action [60]. For the reaction kinetics, see [61].

The exothermic reaction

$$Fe + 5\,CO \longrightarrow Fe(CO)_5(l), \quad \Delta H = -226.92\,kJ/mol$$

is carried out in high-pressure batch equipment with a vertical reactor charged with iron. The gas, circulated by a pump, is preheated and admitted to the reactor. It leaves the reactor hot and loaded with iron pentacarbonyl, which is condensed in a heat exchanger and allowed to expand into the unpressurized purification system under low pressure. To maintain the pressure in the system, the carbon monoxide used is replaced with fresh gas. Most of this is obtained when the carbonyl is decomposed to iron powder. This closed operating cycle removes carbonyl from the reaction equilibrium [62].

Carbon monoxide pressure, temperature, and flow rate are controlled carefully throughout the batch to avoid spontaneous decomposition of carbon monoxide, which would result in a sharp temperature increase and the deposition of carbon black [63].

The liquid carbonyl contains some lubricating oil (from the pump), water, and iron dust. Depending on the starting material, volatile carbonyls of nickel, chromium, molybdenum, and tungsten may also be present. These are removed by distillation.

The batch process is rather expensive and requires inert gas purging at the beginning and end of each batch. Nonetheless, other approaches have not been implemented. In a wet process, carbon monoxide was reacted with solutions of iron(II) salts in aqueous ammonia at 11.5 MPa and 80 °C, giving iron pentacarbonyl in yields of 40 – 50 % [64], [65]. A solution of iron(II) chloride in methanol containing a sulfur compound and Mn powder is said to form iron pentacarbonyl on reaction with carbon monoxide [66]. Another process uses three fluidized beds in series, for iron ore (e.g., hematite) reduction, high-pressure carbonylation, and carbonyl decomposition; however, the process has not been adopted commercially [67], [68].

3.3. Quality Specifications and Analysis

Commercial pure iron pentacarbonyl is brought to high purity by double distillation. The levels

Table 1. Equilibrium data for the formation of iron pentacarbonyl

T, °C	p_{CO}, bar	$Fe(CO)_5$, vol% (at equilibrium)	$K = \frac{(p_{CO})^5}{p_{Fe(CO)_5}}$ Observed	Calculated
60	0.69	22.4	0.86	0.063
80	1.47	21.8	20.1	3.39
160	38.83	9.0	2.4×10^7	1.0×10^5
200	132.68	5.7	5.5×10^9	1.26×10^5

of contaminants, metals that form volatile carbonyls, and sulfur are at or below the threshold of detectability [36].

To test for trace contaminants, a sample is solidified by cooling, treated with excess bromine, and brought slowly to room temperature. After the reaction stops, the residue is dissolved in dilute nitric acid. Techniques suitable for analyzing the solution (e.g., for Cr, Ni, Mo, or Pb) are atomic absorption spectroscopy and emission spectroscopy with inductively coupled plasma. Iron pentacarbonyl can be analyzed in a similar fashion after being dissolved in concentrated nitric acid.

Iron pentacarbonyl in gases, including air, can be oxidized with a hydrogen peroxide–methanol mixture and analyzed as iron hydroxide [36]. Bromine water and concentrated nitric acid are also suitable oxidizing agents. The exposure of individual workers to iron pentacarbonyl is measured by a personal air sampler, consisting of a charcoal-filled tube and a small battery operated gas pump. The iron pentacarbonyl is catalytically oxidized on the activated charcoal to give iron oxide, which can be determined as iron after combustion of the charcoal. The average content of iron pentacarbonyl in the air is then calculated.

Indoor air can be continuously monitored by radiometry with ionization detectors. Iron pentacarbonyl is atomized to an aerosol in a measuring chamber at 150 °C; the aerosol diminishes the ionization current generated by a radioactive source. The change in current is a measure of the carbonyl concentration. The detection threshold is ca. 0.1 ppm [69].

Gas chromatography with an electron-capture detector has been used to determine iron pentacarbonyl and nickel tetracarbonyl in synthesis gas. The detection limit for nickel tetracarbonyl is 0.001 ppm, and that for iron pentacarbonyl somewhat lower [70].

3.4. Safety, Storage, and Transportation

Safety. Two potential hazards must be considered in relation to iron pentacarbonyl: toxicity and combustion. These can be controlled only if the product is handled in sealed equipment [36]. The fire hazard can be summarized as follows:

Flash point	below − 15 °C
Ignition point	<65 °C
Lower explosion limit	2.6–4.5 vol %

On substances with a high surface area, such as activated charcoal, ignition is possible even at room temperature.

Because the heat of combustion of iron pentacarbonyl is only one-fifth that of fuel oil, iron pentacarbonyl fires are easy to extinguish. The best extinguishing agent is water, which removes heat and forms an airtight cover. Water that has been used to extinguish iron pentacarbonyl fires must not be discharged into natural waters.

Iron pentacarbonyl burns completely to iron(III) oxide and carbon dioxide only when it is atomized with air. Open combustion (e.g., in a dish) does not go to completion, and carbon monoxide is formed.

The best protection against the occurrence of iron pentacarbonyl concentrations that might present a danger of poisoning or explosion is continuous air monitoring. Carbon monoxide alarms respond only at much higher, toxic concentrations.

Storage. At industrial plants, iron pentacarbonyl is stored and processed in the absence of air in metallic (usually steel) equipment. Suitable seals and fittings are recommended by the carbonyl producer [36].

In unpressurized tanks, the carbonyl is covered with a protective gas (CO, N_2, Ar, CO_2). Tanks are connected to a gas reservoir so that the pressure does not drop below atmospheric even when the tank is cooled. When the product is stored in pressurized vessels, the liquid is withdrawn through a submerged tube, not through valves in the tank bottom. Tanks and pumps are installed in liquid-tight collecting basins.

Cleaning of Equipment and Disposal. Process equipment can be cleaned before opening by flushing with steam and then condensing the iron pentacarbonyl and water.

Carbonyl residues are collected and reused whenever possible. Because of the density difference, the product can easily be separated from water.

Laboratory carbonyl residues can be collected in a bottle partly filled with water. Glassware is washed several times with a small amount of acetone, which is poured into water for phase separation.

Small amounts of iron pentacarbonyl can be disposed of by burning in a sheet-metal tub. The presence of carbon monoxide in the off-gas must be taken into account.

Transportation. Because of fire and toxicity hazards, stringent regulations apply to the transportation of iron pentacarbonyl. Containers must be airtight and stable.

In Germany, the same regulations apply as in the case of nickel carbonyl. Both substances are assigned to Class 6.1, No. 3 under RID and GGVE for rail shipment, and under ADR and GGVS for road shipment. These regulations allow pressurized containers up to 250 L rated at 1 MPa. They are subject to inspection as pressure vessels (e.g., by TÜV) before being placed in service and at five-year intervals thereafter. The contents are limited to 1 kg of iron pentacarbonyl per liter of capacity. Every pressurized container must bear a nameplate with the following information: name of substance, owner, empty weight, year of first inspection and year of most recent inspection, inspector's stamp, maximum filling weight, and rated pressure (GGVE, Section 604).

The largest producer of iron pentacarbonyl, BASF, sells it in 20- and 250-kg pressurized containers. Each container has two valves or a double valve, so that liquid can be withdrawn through a submerged tube.

Also used as nonreturnable packaging in Europe are 1-L pressurized aluminum bottles, with a rated pressure of 1 MPa and a filling weight of 1 kg.

For international shipment by sea, iron pentacarbonyl is classified as follows: UN No. 1994, Class 6.1, IMDG Code. Air shipment and mailing are forbidden.

Similar regulations now apply in the United States. Although iron pentacarbonyl is a Poison B, because of the risk of inhalation it must be packaged in gas containers under pressure as prescribed for a Poison A under DOT Hazardous Materials Regulations. The containers hold 300 lb of carbonyl.

3.5. Uses

Carbonyl Iron Powder. By far the largest use of iron pentacarbonyl is for the production of carbonyl iron powder.

The equilibrium reaction

$$Fe(CO)_5(g) \rightleftharpoons Fe + 5\,CO, \quad \Delta H = +194.7\,\text{kJ/mol}$$

goes from left to right at standard pressure above 200 °C.

The iron deposited on hot surfaces is brittle, hard, and not commercially usable. In hot liquids such as paraffin oil, finely dispersed iron is obtained [71]. The only process that has become industrially important is decomposition in cavity decomposers, which yields spherical iron particles of 1 – 10 µm diameter [72].

The decomposer is a pipe, externally heated by electricity or gas, into which iron pentacarbonyl vapor is admitted from the top. The carbonyl decomposes not on the wall, which is heated to > 300 °C, but on iron particles circulating in the gas stream. These particles grow to 3 – 8 µm and are then discharged along with the carbon monoxide generated. Carbon and oxygen produced by the decomposition of carbon monoxide are incorporated in the iron. Addition

of ammonia reduces the carbon and oxygen content but leads to incorporation of nitrogen in the iron particles.

The cavity decomposer, invented by BASF in 1924, has not changed fundamentally. A variety of practices have been adopted to control the product, above all its particle size. Fine particles are obtained by admitting oil vapor into the decomposer [73], by diluting the carbonyl vapor with recycled carbon monoxide gas [74], or by applying a temperature gradient from the top to the bottom of the decomposer [75]. Fine particles result if the rate of flow of iron pentacarbonyl is high; larger ones, if the rate is low [76]. Inlet velocity is also a factor [77].

Carbon, nitrogen, and oxygen can be largely eliminated from the iron powder by treatment with hydrogen at ca. 450 °C [78]. The spheres, which were previously very hard (Vickers hardness 800 – 900), become soft (100 – 150 Vickers) and can be deformed by pressure. Hard and soft types are marketed for diverse applications [79].

Carbonyl iron powder is made into magnetic cores for electronic components [80], [81]. Carbonyl iron powder is an important starting material for powder metallurgy (see → Powder Metallurgy and Sintered Materials and → Sintered Steel and Iron: pure iron and iron alloys are made into parts by pressing [82], [83] and by metal injection molding [84–87]. Carbonyl iron powder is also employed for the fortification of foods such as white bread and in the production of iron-containing pharmaceuticals. It is used as a reducing agent in organic chemistry, and is incorporated in rubber or plastic sheets that are used for microwave attenuation [88–90]. For preparation, use, particle-size distribution, and behavior on heat treatment, see [91–95].

Carbonyl Iron Oxide. Only BASF converts iron pentacarbonyl to iron oxides. The processes are harmless to the environment, because the only byproduct is carbon dioxide, and no pollution of the wastewater with salts occurs, unlike when iron oxides are precipitated from solutions of iron salts.

Red iron oxide, in a finely divided form similar to carbon black, is obtained by atomizing iron pentacarbonyl and burning it in an excess of air [96]. By varying temperature and residence time in the reactor, transparent or highly transparent red pigments can be produced [97–99]. The highly transparent pigments are nearly X-ray amorphous and have BET surface areas of 80 – 160 m^2/g. The less transparent grades have surface areas of 10 – 35 m^2/g and clearly show a hematite structure. The iron oxide is used to make high-quality ferrites and similar ceramic materials. Because the content of other metals and electrolytes is extremely low and little energy is needed for dispersion, the oxide is particularly suitable for use as a lightfast, UV-blocking red pigment for paints, wood varnishes, fiber dyeing, and color printing.

Water injection [100] and passage through an intense centrifugal force field [101] during production improve both separation and compactibility.

Air oxidation of iron pentacarbonyl to magnetite is possible at higher temperature [102]. At 100 – 400 °C, magnetic black Fe_3O_4 or brown γ-Fe_2O_3 can be obtained, as desired. The carbon monoxide formed undergoes virtually no oxidation if the reaction takes place in a mechanically agitated fluidized bed of product oxide [103]. Finely dipersed γ-Fe_2O_3 pigments and Fe_3O_4 pigments (particle size 2 – 200 nm) are produced by BASF for use in aqueous suspension as contrasting agents in nuclear magnetic resonance tomography [104].

To obtain mixed oxides with iron as the primary component, iron pentacarbonyl is atomized together with a compound of the other metal (in liquid or dissolved form) that is converted to the oxide at high temperature. For example, by atomizing the carbonyl with an aqueous solution of chromic acid, iron chromium oxide can be obtained for use as a catalyst or as a brown pigment [105], [106].

Other Uses. Polycrystalline iron whiskers can be made by decomposing iron pentacarbonyl in a magnetic field [107–117]. The whiskers are remarkably strong and said to be suitable for making composites or for catalysts. Another process for producing iron whiskers decomposes iron pentacarbonyl in an empty space decomposer above 360 °C [118].

Novel effect pigments ranging from bright yellow to brilliant red are prepared in a fluidized bed of aluminum powder, which is coated with iron oxide when iron pentacarbonyl vapor and air are admitted [119], [120]. Novel

brilliant pigments are produced by coating aluminum flakes with nanometer films of hematite deposited from iron pentacarbonyl and, optionally, a second layer of colorless metal oxide [121]. Other pigments are made on a mica base [122]. These pigments are lightfast and corrosion resistant and are therefore suitable for use in automobile paints.

Carriers for the toner in photocopiers are obtained by coating fine spherical particles of iron or glass [123], respirable plastics [124], or porous silica-containing material [125]. Colored single-component toner powders are made of dispersions of carbonyl iron powder, reflecting pigments or dyes, and other substances in a binder [126], [127].

Suspensions of finely divided iron [128] or its alloys [129] are prepared by decomposing iron pentacarbonyl in solution. This process can be used to produce magnetic liquids [130].

If iron pentacarbonyl is decomposed on, for example, gold ore, the iron deposits preferentially on the metal, which could then be recovered by magnetic separation [131].

Iron pentacarbonyl is not an important industrial catalyst [132]; for its use as a catalyst in organic chemistry, see [133]. Iron pentacarbonyl has been described as a catalyst for the hydrogenation of coal [134], [135]. The catalysis of partial subsurface combustion of heavy crude oil by iron pentacarbonyl, with the aim of lowering the viscosity, has been reported [136], [137].

The complex $Na_2Fe(CO)_4$ formed in solution by the Hieber base reaction [138], recommended long ago for reducing vat dyes [139], has met with renewed interest. For example, chlorate can be removed from diaphragm-cell caustic soda with this product [140]. The use of $Na_2Fe(CO)_4$ to reduce organic compounds is described in [141]. A fuel cell operating with iron pentacarbonyl and an aqueous alkali metal hydroxide of pH < 9 has been proposed [142].

If iron carbonyl is added during thermal degradation of hydrocarbons to carbon fibers, subsequent high-temperature treatment gives a higher yield of better graphitized, more conductive fibers [143].

Pyrite films are obtained from iron pentacarbonyl and sulfur or hydrogen sulfide by chemical vapor deposition. The films are photoactive and can be used to make solar cells [144].

3.6. Economic Aspects

Three companies produce iron pentacarbonyl: BASF (Federal Republic of Germany) with a capacity of over 9000 t/a, GAF (Huntsville, Alabama) with an estimated 1500 – 2000 t/a, and a plant in the former Soviet Union.

These plants also produce carbonyl iron powder, with capacities of ca. 1500 t/a (BASF) and 500 t/a (GAF). The BASF plant has an iron oxide capacity of ca. 1000 t/a.

Consumption of the carbonyl for other purposes is insignificant compared to inplant consumption.

3.7. Toxicology and Occupational Health

Based upon the limited data that is available from laboratory animal studies, iron pentacarbonyl must be classified as highly toxic.

The first laboratory study demonstrated that a 45.5-min inhalative exposure to 0.025 vol % (250 ppm) of iron pentacarbonyl is fatal to rabbits [145]. Studies by BASF showed that 30-min exposure to 40 ppm of iron pentacarbonyl is already lethal to rabbits [146]. Cats reacted with considerably less sensitivity and survived exposure to 300 ppm. In guinea pigs, rats, and mice, fatalitities began after exposure to 140 ppm. After 30-min exposure, LC_{50} values of 2.190 mg/m^3 (275 ppm) for mice and 910 mg/m^3 (115 ppm) for rats were found in later acute toxicity studies [147]. The 4-h median lethal concentration was determined to be 10 ppm in rats [148].

The oral LD_{50} of iron pentacarbonyl is 0.012 mL/kg (0.018 mg/kg) in rabbits and 0.22 mL/kg (0.033 mg/kg) in guinea pigs [149]. After percutaneous application, the LD_{50} in rabbits is 0.24 mL/kg [149]. In BASF experiments, the following LD_{50} values were determined for acute oral toxicity: rabbit, 20 mg/kg; rat, 25 mg/kg; mouse, 100 mg/kg; cat, 100 mg/kg [146]. Iron pentacarbonyl was found to be nonmutagenic in the Ames test. No skin and eye irritation was observed in OECD 404 and OECD 405 tests.

Depending on carbonyl concentration, lethargy, respiratory symptoms, and lung edema

were found in rats in further inhalation experiments [150]. No data are available on the chronic toxicity of iron pentacarbonyl. Only one six-month feeding study with rats, in which 13 mg/d did not lead to any toxic effects, has been reported [151]. The clinical symptomatology of iron pentacarbonyl intoxication is similar to that of nickel carbonyl poisoning. It is marked by immediate onset of disorientation and vomiting. Fever, coughing, and difficulty in breathing occur after 12 – 36 h. Fatalities usually occur 4 – 11 d after exposure to a lethal dose. Pathologic lesions are found in the lungs and in the vascular and nervous systems [152]. Although iron pentacarbonyl and nickel carbonyl intoxications have similar symptoms, iron pentacarbonyl is probably less toxic (see Table 2) [153]. Furthermore, the use of iron pentacarbonyl should result in less exposure than nickel carbonyl because of its lower vapor pressure.

Table 2. Acute rat inhalation toxicity

Substance	LC_{50}, mg/m^3	Exposure time, min
$Ni(CO)_4$	240	30
$Fe(CO)_5$	910	30

Safety precautions are, however, required when working with iron pentacarbonyl to prevent oral, inhalatory, and dermal exposure, because of the relatively high acute toxicity. The MAK value for iron pentacarbonyl is 0.1 ppm. The TLV-TWA is 0.1 ppm (0.8 mg/m^3), as Fe.

4. Iron Compounds, Miscellaneous

Iron Acetates. When scrap iron reacts with acetic acid, it dissolves to form acetate salts [154]. If the initial black solution is concentrated to 12 %, solid *iron acetate* [*2140-52-5*] can be obtained. This salt is a mixture of iron(II) and iron(III) oxidation states of indefinite proportions best formulated as $Fe_x(CH_3COO)_y$. It is used as a catalyst for acetylation and carbonylation reactions.

Pure *iron(II) acetate* [*3094-87-9*], $Fe(C_2H_3O_2)_2$, is colorless. It is used in textile dyeing as an iron base for dark brown, dark blue, and black colors.

Iron(III) acetate [*1834-30-6*], $Fe(C_2H_3O_2)_3$, is prepared industrially by reacting scrap iron with acetic acid, followed by oxidation of the solution with air; it is very sensitive to light. Iron(III) acetate is used for dyeing and printing textiles, as a mordant in dyeing, as a catalyst in organic oxidation reactions, and in dyeing chamois leather.

Basic iron(III) acetate [*10450-55-2*], $Fe(OH)(C_2H_3O_2)_2$, is obtained by boiling a solution of iron(III) acetate and allowing the hydroxy salt to precipitate. This brownish-red compound is used as a mordant in dyeing, for weighting silk and felt, as a conservation additive for timber, and as a colorant for leather.

Iron(II) carbonate [*563-71-3*], $FeCO_3$, forms as a white precipitate when solutions of alkali-metal carbonate salts are added to solutions of iron(II) salts. It is used as a supplement in animal diets and as a flame retardant [154].

Iron Citrates. *Iron citrate* [*2338-05-8*] is a complex of indefinite formula, containing both iron(II) and iron(III). *Iron(II) citrate* [*23383-11-1*] and *iron(III) citrate* [*28633-45-6*] are also of indefinite stoichiometry. *Iron(III) citrate* [*3522-50-7*] (1 : 1 Fe – citric acid) is also known. Iron citrates are readily soluble in hot water and exhibit complex solution chemistry. These compounds have been used as supplements to animal diets and to soil.

Iron(III) ammonium citrate [*1185-57-5*] also has an indefinite formula. The brown hydrated form [*1332-98-5*] contains 16.5 – 18.5 % iron, ca. 9 % ammonia, and 65 % citric acid, whereas the green hydrated form [*1333-00-2*] contains 14.5 – 16 % iron, ca. 7.5 % ammonia, and 75 % citric acid [154]. Iron ammonium citrates are very soluble in water but insoluble in ethanol. They are used as iron additives in food for human consumption (e.g., bread and milk) and for the treatment of iron deficiency in small animals and cattle. They are sensitive to light and are used in light-sensitive paper [154].

Iron Halides. The iron(II) halides (fluoride, bromide, and iodide) are used as catalysts for fluorination, bromination, and iodination in organic reactions. *Iron(II) iodide* [*7783-86-0*] is used as a source of iron and iodine in veterinary medicine.

Iron(III) fluoride [*7783-50-8*] is used as a catalyst in organic reactions. *Iron(III) bromide* [*10031-26-2*] is used in the catalytic bromination of aromatic compounds.

Iron Fumarates. *Iron(II) fumarate* [*141-01-5*], $Fe(C_4H_2O_4)$, is prepared by adding a hot aqueous solution of sodium fumarate to a hot aqueous solution of iron(II) sulfate. It is only slightly soluble in water and can be separated by filtration as a red-brown powder. It is used in human and veterinary medicine in iron supplements. *Iron(III) fumarate* [*52118-11-3*], $Fe_2(C_4H_2O_4)_3$ has also been investigated as a food additive in veterinary studies.

Iron Nitrates. *Iron(II) nitrate hexahydrate* [*14013-86-6*], $Fe(NO_3)_2 \cdot 6\,H_2O$, *mp* 60.5 °C, forms green, rhombohedral crystals. It is prepared by dissolving iron in cold nitric acid ($d < 1.034$ g/cm^3). With increasing density, a greater proportion of iron is oxidized to iron(III). Iron(II) nitrate is used as a catalyst for reductions.

Iron(III) nitrate nonahydrate [*7782-61-8*], $Fe(NO_3)_3 \cdot 9\,H_2O$, forms colorless or pale violet monoclinic crystals. It is made by dissolving iron in nitric acid ($d > 1.115$ g/cm^3).

Iron(III) nitrate hexahydrate [*13476-08-9*], $Fe(NO_3)_3 \cdot 6\,H_2O$, forms colorless, cubic crystals (*mp* 35 °C). Iron(III) nitrate is used as a mordant, in tanning, and as a catalyst for oxidation reactions.

Iron(II) phthalocyanine [*132-16-1*] is synthesized from 1,2-dicyanobenzene and an iron(II) complex in refluxing 1-chloronaphthalene and is purified by sublimation at 450 °C. This green compound is insoluble in most solvents. Because it can exist in many oxidation states, iron(II) phthalocyanine is used as a catalyst for a variety of chemical and electrochemical redox reactions. It is also an important pigment [155].

5. Iron Compounds for the Treatment of Anemia [156], [157]

Sufficient iron in the diet of humans and animals is essential for tissue growth. Iron is found at the active site of many important proteins in the human body. These include hemoglobin (oxygen transport), myoglobin (storage of oxygen), cytochrome c oxidase (converts oxygen to water), cytochrome P450 (hydroxylation of poisonous or unwanted chemicals), and other cytochromes such as cytochrome c (part of the electrontransport system). In addition, iron is necessary for the biosynthesis of iron – sulfur proteins such as rubedoxin.

Although a sufficient amount of iron can usually be found in the diet, the level of absorption of this element from food is generally low. Therefore, the supply of iron can become critical in a variety of conditions. Iron-deficiency anemia is commonly encountered in pregnant women and may also be a problem in the newborn, especially in animal species such as the pig. Some diseases (e.g., rheumatoid arthritis, hemolytic diseases, and cancer) result in poor distribution of iron in the body and thus lead to chronic anemia.

More than 34 iron-containing preparations are used as hematinics for the treatment of iron-deficiency anemia [157]. Oral iron therapy is usually the preferred method of treatment unless good reasons exist for using another route. The daily oral dosage of elemental iron should be 100 – 200 mg. Iron(II) salts are more commonly used than iron(III) salts because they are assumed to be more soluble in the pH range 3 – 7. Solubility is essential if the compound is to permeate cell membranes. The rate of regeneration of hemoglobin appears to be independent of the salt used, provided sufficient iron is given. Factors affecting the choice of preparation are the incidence of side effects and the cost. If side effects occur, an alternative iron preparation or a reduced dosage can be tried. The main iron compounds used in iron supplements are iron(II) fumarate [*141-01-5*], iron(II) gluconate [*299-29-6*], iron(II) sulfate, iron(II) succinate [*10030-90-7*], iron(III) chloride solution, and iron(III) ammonium citrate [*1185-57-5*]. In addition, iron dextran [*9004-66-4*] and iron sorbital [*36134-87-9*] are used in injectable hematinics. Iron(II) sulfate is often preferred because it is the cheapest form and is at least as effective as any other. A number of oral preparations contain ascorbic acid (vitamin C) to stabilize the iron(II) state. However, the therapeutic advantage is minimal and the cost may be increased.

Folic acid is used in conjunction with an iron salt for the prevention of anemia in pregnant women.

Iron(II) complexes have a major disadvantage, however, in that they are sensitive to oxidation, especially in aqueous environments. This can be hindered initially by protectively coating iron(II) compounds in tablet form. However, when they dissolve in the gut, oxidation still occurs to give insoluble iron(III) salts (containing hydroxide). These frequently cause irritation and gastrointestinal distress. Such side effects are often severe, because large doses are neccesary to ensure that enough iron is absorbed. Nausea and epigastric pain may occur and are said to be dose-related, although the relationship between altered bowel behavior (constipation) and dosage is unclear [157].

Soluble iron(III) complexes are thus preferred (because oxidation is not a problem). Unfortunately, such complexes are likely to be charged (which is unsatisfactory for passive membrane diffusion). Even if these complexes were neutral, they may still be toxic.

The ideal properties of an iron(III) chelation complex for treating iron-deficiency anemia are: (1) solubility in the pH range 6 – 9, (2) a ligand with a high affinity for iron(III), (3) a neutral iron(III) complex, and (4) nontoxicity. Furthermore, after absorption into the body the complex must enter into an equilibrium with transferrin (the iron-transport protein) so that iron is available for utilization in metabolic pathways. This means that the chelator must be metabolized rapidly to ensure that iron is freshly available.

Iron(III) maltol [*33725-54-1*], [FeL_3] (maltol(HL) = 3-hydroxy-2-methyl-4*H*-pyran-4-one) and similar complexes [157][158][159][160][161] have been shown to possess the desirable properties outlined above for the treatment of iron-deficiency-related diseases.

Another iron-related disease in humans is severe tissue iron overload. This may occur during the treatment of anemia, mainly as a result of a large number of blood transfusions. This condition is treated by injections of desferrioxamine mesylate, which is a good chelating agent for iron(III), and is also used to treat cases of accidental iron poisoning.

6. Regeneration of Iron-Containing Pickling Baths

In the Federal Republic of Germany in 1987, the output of rolled steel products from base, high-grade, and stainless steels averaged 2.0×10^6 t per month. Approximately 60 % of this is pickled at least once.

Pickling removes the oxide layer that adheres to the steel surface. The oxide layer arises as scale in heat-treatment processes or as rust through the corrosive action of water, with its load of dissolved susbstances, or through humid atmospheric corrosion.

Whereas rust consists largely of Fe_2O_3, scale is made up of the three iron oxides (wustite FeO, magnetite Fe_3O_4, and hematite Fe_2O_3) in a ratio that depends on steel composition, annealing conditions (temperature, heating time, furnace atmosphere), final temperature of rolling, and rate of cooling after rolling.

The "picklability" of a steel and the acid consumption for pickling also depend on many factors: adherence of scale, composition of the steel, mode and magnitude of mechanical working, type and composition of pickling solution, and pickling conditions. The selection of pickling acid is dictated by the required surface quality and by economic factors. The most important pickling acids for iron and steel are sulfuric and hydrochloric. Phosphoric, nitric, and hydrofluoric acids are used for special purposes and stainless steels.

Iron(III) ions that dissolve during pickling are reduced by metallic iron, so that the pickling acid contains primarily iron (II) salts. The quantity of iron dissolved during pickling is called chemical pickling loss; it accounts for 0.2 – 1.2 wt % of the iron or steel being pickled and accounts for approximately three-quarters of the weight loss during pickling.

If iron salts are removed from the pickling liquor, the unconsumed pickling solution can be returned to the pickling unit after the addition of an amount of acid equivalent to the quantity of salts precipitated.

The acid consumed in pickling can also be completely regenerated from the iron salts. The pickling liquor recycled between the pickling tanks and the regeneration unit is thus not consumed, apart from evaporation losses.

6.1. Sulfuric Acid Pickling Solutions

When steel is pickled with sulfuric acid, the scale oxides dissolve to give iron sulfates. The rate of dissolution of the three oxides in sulfuric acid increases in the order Fe_2O_3, Fe_3O_4, FeO. The reaction of sulfuric acid with metallic iron to give iron(II) sulfate and hydrogen is inhibited by pickling additives (inhibitors).

Two processes are employed to regenerate sulfuric acid pickling liquor:

1) Crystallization of iron(II) sulfate heptahydrate
2) Complete regeneration by electrolysis

6.1.1. Crystallization

In industrial plants, spent pickling solution is usually cooled by using brine. The cooling effect depends strongly on the cleanness of the cooling surface, on which salt crust can easily form. These systems, therefore, require very careful upkeep. Frequent shutdowns must be expected.

Vacuum Crystallization (Fig. 1). A vacuum equal to the vapor pressure of water at the desired final temperature is maintained in the crystallization vessel.

Figure 1. Vacuum crystallization (Keramchemie/Lurgi)
a) Suction tank; b) Precooler; c) Precooler; d) Crystallizer; e) Steam-jet compressor; f) Salt-slurry pump; g) Thickener; h) Centrifuge; i) Direct-contact condenser; j) Auxiliary condenser; k) Steam-jet venting device; l) Vacuum pump; m) Water receiver; n) Pickling solution receiver; o) Acid direct-contact condensers

Part of the pickling solution is pumped continuously from the pickling tank to the vacuum crystallizer, where it is cooled evaporatively to 5 °C and then to 0 °C to crystallize iron(II) sulfate. Water vapor flows directly, or after compression in a high-performance steam-jet apparatus, to a direct-contact condenser. The salt–liquid mixture is removed continuously by a salt-slurry pump and separated in a centrifuge. After the mother liquor has been freshened with concentrated sulfuric acid and water, it is returned to the pickling tank. The vacuum in the evaporator is maintained by a vacuum pump connected to the direct-contact condenser.

A modified design omits the steam-jet apparatus; therefore, only electrical energy is needed for its operation, which may be an economic advantage because in this case no fuel is required for steam generation.

Cyclone Crystallization (Fig. 2). In the cyclone crystallizer (b), fine droplets of spent pickling solution are sprayed countercurrent to a stream of air. In this way, rapid evaporation and cooling are accomplished. If the iron content of the pickling solution is to be kept low, a second cooling stage is added. Indirect cooling with water or brine takes place in the cooling vessel (c). A blower injects air to prevent the crystals from settling and forming a crust on the vessel wall. Iron(II) sulfate crystals are separated in the centrifuge (d); the filtrate (regenerate) is returned to the pickling plant.

Figure 2. Cyclone crystallizer (Andritz-Ruthner)
a) Acid pump; b) Cyclone crystallizer; c) Cooling vessel; d) Centrifuge; e) Vent; f) Blower; g) Pickling liquor tank; h) Cooling system

The iron(II) heptahydrate can be used in the production of cyanoferrates, as a flocculant in

wastewater treatment, in the production of gas adsorbents, as a pesticide, as a chemical fertilizer, and in the production of iron-oxide pigments.

The heptahydrate can also be converted to the monohydrate. A continuous apparatus for the preparation of very pure monohydrate is built by Mannesmann Anlagenbau/Messo-Chemietechnik.

The heptahydrate is dehydrated to the monohydrate at a well-defined acid concentration at ca. 90 °C. After separation of the crystalline monohydrate in a centrifuge, iron sulfate-poor mother liquor is returned to the reactor. The water vapor resulting from the dehydration is removed from the cycle.

6.1.2. Electrolysis

An electrolytic process has been developed [162]. Cathode and anode compartments are separated by a diaphragm (Fig. 3). Metallic iron is deposited at the cathode; sulfuric acid and oxygen are produced at the anode. Electrolysis is facilitated by addition of an electrolyte, which is not consumed and does not affect the pickling process, but allows iron to be recovered most effectively from the acidic solution. Sulfuric acid either flows directly from the anode compartment back to the pickling tank or is detained temporarily in a holding tank.

Figure 3. Regeneration by electrolysis
a) Pickling tank; b) Electrolysis cell; c) Diaphragms; d) Cascade rinsing; e) Spent pickling solution

Evaporation and electrochemical decomposition result in a continual loss of water. Using multiple countercurrent cascade rinsing after pickling allows the quantity of water to be adjusted so that no wastewater is produced. The unit is marketed by Keramchemie.

6.2. Hydrochloric Acid Pickling Solutions

Because of its technical advantages, hydrochloric acid has largely replaced sulfuric acid in pickling baths, especially in large plants.

Hydrogen is produced when iron is dissolved. Iron(III) chloride, formed by dissolution of Fe_3O_4 and Fe_2O_3, is reduced by the hydrogen to yield $FeCl_2$, so that virtually the only chloride present in the pickling liquor is iron(II) chloride. Spent pickling solution can be regenerated completely by thermal decomposition. Iron chloride is converted to iron oxide and hydrochloric acid:

$$4\,FeCl_2 + 4\,H_2O + O_2 \longrightarrow 2\,Fe_2O_3 + 8\,HCl$$

Gas or oil is used as fuel. The heat consumption is ca. 3 MJ for the simultaneous regeneration of 1 L of pickling solution and 1 L of rinse liquor.

In large-scale operations, the two processes that have found widespread application are 1) the fluidized-bed process and 2) the spray-roasting process.

Each is employed in more than 100 industrial plants. The efficiency of the acid recovery is ca. 99 %.

Fluidized-Bed Process. In the Lurgi–Keramchemie fluidized-bed regeneration process [163] (Fig. 4), spent pickling solution is led via the settling tank and the venturi loop into the fluidized bed in the reactor. The bed consists of granulated iron oxide. Residual acid and water are evaporated at 850 °C, and iron chloride is converted to iron oxide and hydrogen chloride. Growth and new formation of iron oxide grains in the fluidized bed are controlled so that a dust-free granulated product is obtained, with a particle diameter of 1 – 2 mm and a bulk density of ca. 3.5 g/cm^3. The granular product is discharged continuously at the bottom of the reactor and transported by a vibrating cooling chute and a vibrating spiral conveyor to the storage bin. In smaller units, the granular product can also be discharged directly into shipping containers.

Figure 4. Fluidized-bed process for regeneration of hydrochloric acid pickling solutions
a) Separating tank; b) Venturi scrubber; c) Reactor; d) Cyclone; e) Absorber; f) Scrubbing stage; g) Off-gas blower; h) Stack; i) Mist collector

The hot gases from the reactor contain hydrogen chloride and a small amount of iron oxide dust, which is collected in the cyclone and returned to the fluidized bed. In the venturi scrubber, the off-gas is then cooled to ca. 100 °C. The thermal energy of the off-gases is used to concentrate the pickling solution by evaporation before it is fed to the reactor. Fine dust particles in the gas stream are removed by scrubbing.

From the venturi scrubber, the cooled gas stream goes to the absorber, where hydrogen chloride is absorbed adiabatically with rinse liquor and fresh water. The hydrochloric acid thus produced has a concentration of ca. 18 %. It is recycled to the pickling unit or held in a storage tank. After passing through a scrubbing stage and a mist collector, the off-gas is virtually free of hydrochloric acid and is released to the atmosphere.

Spray-Roast Process. The spray-roast process is often employed for the recovery of metal oxides from metal chloride solutions. It can also be used for the regeneration of iron chloride-laden hydrochloric acid solution [164]. The pure spray-roast oxide obtained in this way is used in the ferrite industry (150 000 t in 1987).

As shown in Figure 5, spent pickling solution goes to the venturi scrubber where hot gases concentrate it by evaporation of water. In the next step, the highly concentrated pickling liquor is injected into the spray-roast reactor at a pressure of 0.3 – 0.5 MPa as a fine spray either cocurrent or countercurrent to hot combustion gases. The cocurrent arrangement is common for pickling acids that contain zinc and lead, because their chlorides have high vapor pressures and are separated after a shorter retention time.

Figure 5. Spray-roast process for regeneration of hydrochloric acid pickling solutions
a) Venturi scrubber; b) Spray-roast reactor; c) Cyclone; d) Absorber; e) Rinse tanks; f) Pickling tanks

The temperature of the roasting gas outlet from the spray tower is about 400 °C. The gases proceed to the cyclone. Fine iron oxide powder, together with the oxide collected in the cyclone, is discharged continuously (bulk density 0.3 – 0.4 g/cm^3).

When some silicon-rich steels are pickled, the silicon dioxide content of the pickling solution does not permit the iron(III) oxide product to be used in the ferrite industry. The quantity of silica can be reduced in an additional precleaning step [165], in which silica is selectively removed from the pickling solution.

After passisng through the cyclone, the roasting gases are cooled and scrubbed in the venturi scrubber before going to the absorber, where hydrogen chloride is absorbed to produce 18 – 20 % hydrochloric acid. The acidic iron chloride solution, which is generated when the pickled steel is rinsed, is used as the absorption liquor. Hydrochloric acid is recycled to the pickling tank. Residual gases, with a low hydrochloric acid content, are discharged to the atmosphere.

Spray-roast plants have unit capacities of 0.3 – 25 m^3/h of pickling acid and a similar amount of rinse liquor.

The Fe_2O_3 generated in the thermal decomposition process can be used as raw material in various industries. The most important options are the production of magnetic materials (e.g., soft and hard ferrites), the production of iron powder for the fabrication of sintered parts and welding electrodes, and use as an additive in the

manufacture of magnetic tapes, abrasives, tiles, glass, cosmetics, and pigments.

6.3. Nitric and Hydrofluoric Acid Pickling Solutions

Stainless and acid-resistant steels are usually pickled with a mixture of nitric and hydrofluoric acids. Nitric acid serves as an oxidizing agent, whereas hydrofluoric acid forms complexes with metal ions. In contrast to the pickling of carbon steel, the permissible iron concentration in a pickling solution for special steels is limited by the tendency of iron and the alloy components to form fluoride complexes and thus reduce the concentration of fluoride ions in solution. Severe inhibition of the pickling process occurs at a total metal concentration of 50 g/L, so that pickling solutions must be topped up with fresh hydrofluoric acid, and eventually neutralized and discarded, even though only about half the acid content has been consumed.

When the pickling bath is neutralized with calcium hydroxide, the resulting metal hydroxides and calcium fluoride form a sludge that can be disposed of without treatment, but nitrates remain in solution and contribute to eutrophication in receiving waters.

The following regeneration processes have been devised:

1) Liquid – liquid extraction
2) Fluoride crystallization
3) Bipolar membrane process
4) Retardation process

Liquid – Liquid Extraction. Liquid – liquid extraction [166] makes use of the fact that nitric and hydrofluoric acids form adducts with tributyl phosphate that are soluble in hydrocarbon solvents. Addition of sulfuric acid also renders extractable acid anions bound in the form of metal salts. Around 93 % of the nitric acid and 60 % of the hydrofluoric acid can be recovered. The flow sheet for the process is shown in Figure 6.

Figure 6. Regeneration of HF – HNO_3 pickling liquors by liquid – liquid extraction
a) Heat exchanger; b) Extraction column; c) Storage tank; d) Reextraction column; e) Storage tank; f) Adsorber

After sulfuric acid has been added to the spent pickling solution and the mixture has been cooled, it is directed to the top of an extraction tower; the organic phase enters at the bottom. The aqueous raffinate, containing sulfuric acid, is discharged at the bottom. From the top of the tower, the organic phase, laden with extracted acid, goes to the foot of a re-extraction tower. The water inlet at the top washes out the acids. The organic phase discharged at the top goes back to the extraction tower. In an adsorber, traces of tributyl phosphate are removed from the aqueous regenerate before it is returned to the pickling tank. The tributyl phosphate is returned to the tank (c).

Fluoride - Crystallization. In this process, the recovery of nitric acid is ca. 90 % (Fig. 7) and that of hydrofluoric acid, 55 %, despite the fact that metals precipitate as fluorides, so that corresponding amounts of hydrofluoric acid are consumed. The filter residue can be employed as a feedstock for the production of hydrofluoric acid or for the recovery of nickel.

Spent pickling solution is led through a particulate collector and a flow-through evaporator, where it is evaporated within minutes to about half its volume by electrical heating. The water vapor, which contains part of the nitric and hydrofluoric acids, is condensed by indirect cooling. The sparingly soluble fluorides of iron and of the alloy constituents precipitate from the concentrated, supersaturated solution in crystallization tanks and are removed periodically by

filtration. The filtrate is led to a storage vessel where it is combined with condensate from the condenser. After addition of fresh nitric and hydrofluoric acid, the liquor is returned to the pickling tank.

Figure 7. Regeneration of HNO_3–HF pickling solutions by fluoride crystallization
a) Particle collector; b) Flow-through evaporator; c) Condenser; d) Crystallization tanks; e) Filter; f) Storage tank

Bipolar Membrane Process. In the bipolar membrane process [167] (Fig. 8), the free acids are first recovered in an electrodialysis cell and then returned to the pickling tank. Metal ions are then precipitated as metal hydroxides by neutralization with potassium hydroxide. Metal hydroxide sludge is collected in the downstream filter press. The filtered salt solution (potassium fluoride and potassium nitrate) goes to a bipolar membrane module where HF, HNO_3, and KOH are separated from the potassium salts. The acid mixture is returned to the pickling tank, whereas potassium hydroxide is reused for neutralization. The dilute salt solution (KF, KNO_3) is desalted by reverse osmosis. Part of it is used as wash liquor for the filter press, and the rest is recycled to the membrane unit to obtain the highest possible yield of acids and potassium hydroxide. The residue from the filter can be reused as raw material in iron and steel works, depending on its content of metal hydroxides.

Figure 8. Regeneration of HNO_3–HF pickling solutions in a bipolar membrane cell
a) Pickling tank; b) Electrodialysis cell; c) Neutralization; d) Filter press; e) Bipolar membrane module (Aquatech cell); f) Reverse osmosis

Retardation Process. The retardation process can generally be employed for separating strong inorganic acids from their salts. By loading a strongly basic ion-exchange resin with spent pickling solution and then eluting with water, separation into a high-salt fraction and a subsequent high-acid fraction is achieved. The flow sheet for the process is shown in Figure 9.

Figure 9. Regeneration of HNO_3–HF pickling solutions by acid retardation
a) Sedimentation tank; b) Buffer tank; c) Pickling-liquor metering tank; d) Water metering tank; e) Resin bed

Acid retardation can probably be accounted for by diffusion of undissociated acid into the ion-exchange resin grains so that upon elution with water, it must diffuse back out; the result is that elution of acid is retarded [168].

For nitric and hydrofluoric acid pickling solutions, most of the free acids can be recovered in this way. Partial regeneration of pickling solutions reduces disposal costs.

1. Introduction

Organic isocyanates are esters of isocyanic acid with the formula R–N=C=O. The first synthesis of an organic isocyanate was reported by A. WURTZ in 1848. Prominent chemists, including A. W. VON HOFMANN and T. CURTIUS, investigated the chemistry of organic isocyanates in the 1800s. The commercially important synthesis of isocyanates from amines and phosgene was discovered by W. HENTSCHEL in 1884 [1]. Diisocyanates became commercially important in the 1930s when the addition polymerization of difunctional isocyanates and polyols to produce polyurethanes was discovered by O. BAYER and coworkers at the I.G. Farben laboratories in Leverkusen [2]. More than 270 isocyanates were synthesized between 1934 and 1949 [3]. Today, 4,4′-diphenylmethane diisocyanate (MDI), toluene diisocyanate (TDI), hexamethylene diisocyanate (HDI), isophorone diisocyanate (IPDI), hydrogenated MDI [bis(4-isocyanatocyclohexyl)methane, H_{12}MDI], and derivatives thereof are of major practical importance.

2. Physical Properties

Organic isocyanates are colorless liquids or low-melting solids; they are normally purified by distillation. Excessive heating should be avoided because thermal degradation, sometimes accompanied by evolution of carbon dioxide and carbonization of the residue, and formation of oligomeric products may occur due to the high reactivity of the isocyanate group. The more volatile isocyanates are strong lacrimators with high inhalation toxicity; exposure should therefore be avoided. Polymeric MDI products are dark liquids; the viscosity depends on the diisocyanate content. Some physical properties of commercially available mono- and diisocyanates are listed in Tables 1, 2, and 3. The boiling and melting points of a variety of diisocyanates have been tabulated [3].

3. Chemical Properties

For general information, see [4–6].

Reaction with Nucleophiles. The reactivity of isocyanates is evident from the electronic resonance structures (Eq. 1).

$$\mathrm{R{-}N{=}C{=}O} \longleftrightarrow \mathrm{R{-}N^{-}{-}\overset{+}{C}{=}O} \longleftrightarrow \mathrm{R{-}N{=}\overset{+}{C}{-}O^{-}} \quad (1)$$

As a result, nucleophilic reagents rapidly attack the electrophilic carbon atom of the isocyanate group. Aromatic isocyanates react more rapidly than their aliphatic congeners, primarily for electronic reasons. The rate of reaction is further increased by electron-withdrawing substituents on the aromatic ring and decreased by electron-donating substituents. Steric hindrance also influences the rate of reaction. Aliphatic isocyanates react in the rate order primary > secondary > tertiary. Aromatic isocyanates with substituents adjacent to the isocyanate group also react more slowly because of steric hindrance. Thus, 2,4-toluene

diisocyanate reacts with nucleophiles preferentially at the 4-position. Steric hindrance in the attacking nucleophile similarly influences reaction rate: alcohols react in the order primary > secondary > tertiary. The reactivity of an attacking nucleophile is proportional to its nucleophilicity: aliphatic amines > aromatic amines > alcohols > thiophenols > phenols. The reactivity of the slower reacting phenols and thiophenols can be increased considerably by using the corresponding anions, but side-reactions may occur (e.g. trimerization; see page 8).

Commercially, the most important nucleophilic reaction of isocyanates gives addition or condensation polymers. Reaction with polyether or polyester polyols produces polyurethanes (→Polyurethanes); reaction with polyamines gives polyureas; reaction with dicarboxylic acids yields polyamides (→Polyamides); and reaction with carboxylic acid dianhydrides results in polyimides (→Polyimides).

The reaction of isocyanates with alcohols to form carbamates is catalyzed by tertiary amines and a variety of metal-containing catalysts, most prominently organotin compounds. The carbamates dissociate on heating (Eq. 2).

$$R^1N{=}C{=}O + R^2OH \rightleftarrows R^1NHCOOR^2 \quad (2)$$

The thermal stability of polyurethanes is therefore limited by the reversibility of this reaction. Use is made of this thermal instability in so-called blocked isocyanates, which contain the rather reactive NCO group in a deactivated form. Adducts of isocyanates with phenols, ketoximes, malonic esters, N heterocycles, etc. are examples of these blocked isocyanates. They are preferably used in coatings [7], [22].

The reaction of isocyanates with water gives a carbamic acid as an unstable intermediate, which undergoes decarboxylation to produce carbon dioxide and the corresponding amine (Eq. 3); the latter immediately reacts with more isocyanate to yield a symmetrically disubstituted urea (Eq. 4).

$$RN{=}C{=}O + H_2O \longrightarrow [RNHCOOH] \longrightarrow RNH_2 + CO_2 \quad (3)$$

$$RN{=}C{=}O + RNH_2 \longrightarrow RNHCONHR \quad (4)$$

Following the discussions about the role of chlorofluorocarbons (CFCs) in the depletion of the ozone layer in the early 1990s, this reaction with water is nowadays made use of in the production of flexible polyurethane foam from toluene diisocyanate and polyether polyols. The carbon dioxide generated then acts as a blowing agent [8], that is, as a CFC substitute.

Use can also be made of the NCO – water reaction in the manufacture of biuret-type aliphatic polyisocyanates. The final product, a biuret, is the addition product of isocyanate to urea (Eq. 5).

4-Toluenesulfonyl isocyanate undergoes very fast reactions with nucleophiles. This isocyanate is used as a water scavenger. Thus, 4-toluenesulfonamide is formed (Eq. 6), which does not undergo reaction with a second molecule of isocyanate.

$$MeC_6H_4SO_2N{=}C{=}O + H_2O \longrightarrow MeC_6H_4SO_2NH_2 + CO_2 \quad (6)$$

The reaction of isocyanates with amines (Eq. 7) to give disubstituted ureas is very fast and quantitative. For example, the reaction with excess di-*n*-butylamine is used for quantitative determination of isocyanate content (see Chap. 6) [9].

$$R^1N{=}C{=}O + R^2_2NH \longrightarrow R^1NHCONR^2_2 \quad (7)$$

The rate of reaction of isocyanates with amines increases with increasing basicity of the amine. Sterically hindered or electronically deactivated aromatic diamines are used as chain extenders in segmented polyurethane elastomers to achieve suitable reaction rates [7]. The only application of amine-type reaction partners for the isocyanate component in coatings applications, where the use of aromatic amines (and isocyanates) is in most cases less favourable due to discoloration of the final product, are aspartic acid esters (Eq. 8, adducts of diamines to maleic acid esters) [10].

(8)

Carboxylic acids react with isocyanates to give mixed anhydride intermediates, which are decarboxylated to give amides at elevated temperature (Eq. 9).

(9)

Base catalysis is required to avoid formation of disubstituted urea byproducts. The reaction of suitable carboxylic acid anhydrides, such as phthalic, trimellitic, pyromellitic, and benzophenonetetracarboxylic acid dianhydride, with isocyanates to give imides is catalyzed by nucleophiles [11].

Hydrogen halides form carbamic acid halides with isocyanates, which are thermally labile (Eq. 10).

X = halogen (10)

Carbamic acid chlorides (X = Cl) are the thermally labile intermediates in the production of isocyanates from amines and phosgene (see Section 4.1).

Organic isocyanates undergo addition reactions with molecules containing active hydrogen atoms (e.g., Michael-type substrates, Eq. 11).

(11)

Insertion reactions occur with a variety of substrates containing metal – oxygen, metal – sulfur, or metal – nitrogen bonds. This reaction is observed with elements of Groups 1, 2, 12, and 13 [6].

Cycloaddition Reactions. Isocyanates undergo cycloaddition, in most cases across the carbon – nitrogen bond, with a variety of substrates containing double or triple bonds. Dimerization (Eq. 12) and trimerization (Eq. 13) are also examples of this type of reaction. Additions across the C=O bond are rare. An example is the formation of iminooxadiazinedione trimers (Eq. 14) [12], [13].

uretdione (12)

isocyanurate (13)

iminooxadiazinedione (14)

Slow dimerization occurs during storage [14] and may be accelerated at elevated temperature. Aromatic isocyanates dimerize and trimerize more readily than aliphatic isocyanates. Dimerization is catalyzed by pyridines and phosphines. Strong bases such as tertiary amines, hydroxides, or carboxylates catalyze trimerization to isocyanurates. Iminooxadiazinediones are side products in most known trimerization reactions. (Poly)fluorides, however, lead to a significant higher content of iminooxadiazinedione in the mixture of trimers [13]. The trimerization of PMDI is used in the manufacture of rigid polyurethane foams with higher thermal stability and better combustibility characteristics [9]. The cycloaddition of isocyanates with carbodiimides is used in the production of carbodiimide-modified liquid MDI products (see Chap. 8).

The conversion of isocyanates to carbodiimides (Eq. 15) is catalyzed by phospholene oxides and other species containing a P=O group [15].

$$2\,RN{=}C{=}O \longrightarrow RN{=}C{=}NR + CO_2 \qquad (15)$$

Isocyanates also undergo anionic homopolymerization. The reaction is preferred at low temperature and is to some extent reversible, provided the polymer has not aged. Catalysts used include sodium cyanide in DMF and aqueous solutions of alkali metal salts [16] but several other "dimerization" and "trimerization" catalysts described above also convert isocyanates at low temperature to 1-nylons (Eq. 16).

(16)

1-Nylon type isocyanate homopolymers have not found commercial use so far. Reviews on isocyanate derivatives are available [17], [18].

4. Production

For general information, see [3], [8], [19–21].

Isocyanates in general can be prepared in many ways. Besides some well-known laboratory-scale methods, among which are the Curtius, Hofmann, and Lossen rearrangements via nitrene intermediates, a number of special syntheses are available [6], [23], [73], [74]. Most of these methods, however, are not satisfactory for large-scale operation. The reaction of phosgene with amines or amine salts and the thermal cleavage of urethanes, preformed from the appropriate amine, urea, and an alcohol, are used commercially on a large scale [24], [25].

The production chain to polyurethanes using TDI and/or MDI is portrayed in Figure 1.

Toluene is the primary raw material for industrial TDI manufacture. The classical dinitration of toluene with mixed acid produces a mixture of the 2,4- and 2,6-dinitro isomers in a ratio of 80:20. Catalytic reduction of these derivatives under hydrogen pressure leads to the corresponding diamines TDA [26–31], which are subsequently treated with phosgene to give TDI [32], [33].

The production of PMDI involves condensation of aniline with formaldehyde in the presence of hydrochloric acid to give oligomeric di- and polyamines that are phosgenated without further need of purification (→Aniline, Chap. 6.1.). The percentage distribution of the homologues and isomers of MDA depends on the ratio of aniline to formaldehyde, the acid concentration, and the reaction conditions [34]. Monomeric MDI is obtained from PMDI by continuous thin-film distillation. The residual crude oligomeric isocyanate product (PMDI) is used mainly in the production of rigid polyurethane or polyisocyanurate foams that usually find use in insulation, construction, or automotive applications. Yields in the production of PMDI – MDI are quantitative. The production of aromatic amines used in the manufacture of TDI and PMDI is described in [22], [23].

The most common aliphatic diisocyanates are hexamethylene diisocyanate (HDI), isophorone diisocyanate (IPDI), and hydrogenated MDI (H_{12}MDI). They are industrially made from the corresponding amines (HDA, IPDA, and H_{12}MDA) by reaction with phosgene or by the carbamate route (reaction of the amine with urea and alcohol). Hydrogenated MDI is produced by catalytic hydrogenation of methylenedianiline (MDA) on a rhodium or ruthenium catalyst to yield a mixture of *trans*,*trans*-, *cis*,*trans*-, and *cis*,*cis*-H_{12}MDA, which is then phosgenated (Eq. 17).

(17)

For conversion to pure *trans*,*trans*-H_{12}MDA, see [35], [36]. To obtain a liquid diisocyanate product in the subsequent phosgenation, the amount of *trans*,*trans*-H_{12}MDA, which is solid in the pure state, has to be reduced to ca. 20 % (selective hydrogenation and/or crystallization).

4.1. Phosgenation of Free Amines

The reaction of free amines with phosgene is by far the most efficient and economically attrac-

Figure 1. Industrial route to TDI and MDI (for the sake of clarity, only one isocyanate isomer is shown)

tive method for large-scale production of isocyanates. Depending on the boiling point and the basicity of the free amine, phosgenation can be carried out in the liquid or gas phase.

Solvents used in the phosgenation of free amines include hydrocarbons such as toluene, xylene, decalin (decahydronaphthalene), chlorobenzene, and *ortho*-dichlorobenzene. Chlorinated hydrocarbons are preferred because of their higher polarity, which aids in dissolution of the amine hydrochlorides. The overall reaction is shown in Equation (18).

(18)

For the phosgenation of aromatic (poly)amines such as TDA or PMDA in a batch process, a 10 – 20 wt % solution of the amine is prepared in monochlorobenzene or *ortho*-dichlorobenzene and is thoroughly mixed with excess liquid phosgene or a solution of phosgene (100 – 500 % phosgene excess) in the same solvent at ambient temperature. The reaction mixture is heated and excess phosgene and HCl byproduct are purged by a nitrogen flush. Phosgene can be regarded not only as a reactant but also as a solvent. The amount of excess phosgene necessary to achieve optimum isocyanate yield depends on the number of amine groups and, in case of polyamines, the differences in reactivity between these groups: the more the reactivities of the different amino groups of a compound differ, the more residence time, dilution, and phosgene excess is usually needed. As soon as evolution of hydrogen chloride is complete and a homogeneous solution is obtained, the solvent is removed by distillation, and the pure isocyanate is obtained by fractional distillation, crystallization, or sublimation.

In continuous isocyanate production processes the same raw materials are mixed to produce a slurry of the corresponding carbamic acid chloride. This slurry is pumped into a reactor or a series of reactors where the reaction to give the free isocyanate is completed [32]. The temperature in the first reactor is usually in the range of the dissociation temperature of the carbamic acid chloride (< 80 – 100 °C), and the subsequent reaction is conducted above 150 °C to complete the evolution of hydrogen chloride and formation of isocyanate. Hydrogen chloride and excess phosgene are vented at the higher temperature to prevent recombination of hydrogen chloride with the isocyanate. Phosgene and hydrogen chloride are recovered [37], [38] (see Chap. 5). The waste gas, containing small amounts of phosgene, is hydrolyzed with water on charcoal, whereby traces of organic solvents are also adsorbed. The isocyanate raw product is purified by fractional vacuum distillation; the stripped solvents are reused. Usually the distillation residue is incinerated after polymerization

to give solid particles [39–41] or hydrolyzed to recover part of the amines [42–46].

In the case of PMDI the byproducts formed during phosgenation may remain in the product [47]. Though these byproducts influence the reactivity of the crude polyisocyanate, because hydrolyzable chlorine compounds (e.g., *N*-chloroformylchloroformamidines; see Eq. 22) deactivate the amine catalysts used in polyurethane production. The coproduct MDI is recovered by thin film evaporation. In this manner, a mixture consisting of ca. 99 % 4,4′-MDI and 1 % 2,4′-MDI is obtained. For some applications, production of MDI with higher amounts of the 2,4′ isomer is preferred. This is best accomplished by conducting the aniline – formaldehyde condensation at higher temperature, which favors formation of the 2,4′ and 2,2′ isomers.

For the production of aliphatic isocyanates, continuous free amine phosgenation processes in liquid phase are unsuitable because of the slower reaction rates observed for aliphatic amine hydrochlorides and side reactions resulting from the higher basicity of aliphatic amines. Two-phase phosgenation with an inert solvent and an aqueous phase containing a base (as the hydrogen chloride scavenger) is feasible for aliphatic amines. In general, aliphatic diisocyanates are produced either by phosgenation of a slurry of the corresponding amine hydrochlorides (see Section 4.2) or of the carbamate salts obtained by the reaction of the aliphatic diamines with carbon dioxide (see Section 4.2), through phosgenation in the gas phase [48–54], or by non-phosgene routes (see Section 4.3). Exceptions are longer chain aliphatic isocyanates, such as octadecyl isocyanate, 1,12-dodecane diisocyanate, and the diisocyanate obtained from dimer acid (→Dicarboxylic Acids, Aliphatic, Chap. 3.4.2.). Longer alkyl chains increase the solubility of the corresponding hydrochlorides in hydrocarbon solvents. Thus, the reaction rates necessary for continuous phosgenation of the free amine can be obtained.

As discussed earlier the phosgenation reaction is typically conducted in highly diluted solutions, since in most cases the solubility of the amine is low and the formation of urea can be suppressed by dilution. Disubstituted ureas are formed as byproducts by reaction of the isocyanate with unconverted amine. In the case of an aliphatic amine, the urea reacts further with phosgene to form allophanoyl chlorides (Eq. 19), which can be thermally converted to isocyanates (Eq. 20) [55].

(19)

(20)

For aromatic amines, the urea byproducts can be dehydrated by phosgene to form carbodiimides (Eq. 21), which then react with excess phosgene to give *N*-chloroformylchloroformamidines (Eq. 22); cycloadducts of carbodiimides with isocyanates are also formed (Eq. 23).

(21)

(22)

(23)

Cycloadducts with 4-membered rings can be cleaved by thermal treatment.

4.2. Other Phosgenation Procedures

Phosgenation of Amine Hydrochlorides. One method used to avoid side reactions is the phosgenation of amine hydrochlorides, rather than the free amine, exemplified by the conversion of isophorone diamine dihydrochloride to isophorone diisocyanate [56]. Isophorone diamine in decahydronaphthalene solution flows downward against a hydrogen chloride gas stream. The fine slurry of amine salts obtained is heated to 150 °C and treated with phosgene in a series of agitated autoclaves to give a clear solution of isophorone diisocyanate. Excess phosgene is removed by purging with nitrogen. Isophorone diisocyanate is isolated by stripping off the solvent and fractional vacuum distillation of the residue.

In the phosgenation of aliphatic diamine dihydrochlorides, the reaction has to be conducted below 150 °C to avoid the formation of ω-chloro monoisocyanates because of cleavage of the NCO group by hydrogen chloride [3].

Phosgenation of Carbamate Salts. Carbamate salts can be used instead of aliphatic amine hydrochlorides to achieve faster reaction [57–59]. For example, hexamethylenediamine and *ortho*-dichlorobenzene are introduced into a cooled reaction vessel and stirred at 5 – 10 °C under 0.5 atm CO_2 pressure to form a suspension of the carbamate salt. This suspension is subsequently transferred into a reactor containing a phosgene solution. Similarly, tetramethylene diisocyanate can be prepared. The recovery of phosgene and hydrogen chloride and workup of the reaction mixture are similar to other phosgenation processes.

Phosgenation of Ureas. Phosgenation of disubstituted ureas [60], [61] is used in the production of arenesulfonyl isocyanates. Direct phosgenation of sulfonamides proceeds in polar solvents only above 200 °C, whereby significant amounts of arenesulfonyl chlorides are formed as byproducts. In contrast, 1-arenesulfonyl-3-alkylureas undergo rapid reaction with phosgene at ca. 150 °C [62] . In the commercial production of arenesulfonyl isocyanates, reaction of the sulfonamides is conducted in the presence of a catalytic amount of *n*-butyl isocyanate (Eq. 24) to achieve rapid rates at 150 °C [63]. The rate-determining step is the intermediate formation of the urea. The *n*-butyl isocyanate catalyst is regenerated in the phosgenation of the urea (Eq. 25).

(24)

(25)

The reaction of disubstituted ureas (Eq. 26) with phosgene can also be used to synthesize aliphatic isocyanates which contain groups such as esters or ethers that are sensitive to prolonged heating with phosgene. The lower boiling aliphatic isocyanate R^2NCO is continuously removed from the reaction mixture (Eq. 27) [64].

(26)

(27)

Arenesulfonyl isocyanates are used as intermediates for pharmaceuticals and herbicides, and as water scavengers in the formulation of coating systems.

4.3. Non-Phosgene Processes

On a laboratory scale, liquid trichloromethyl chloroformate (diphosgene) [65], solid bis(trichloromethyl) carbonate (triphosgene) [66], or solid di-*tert*-butyl tricarbonate ("pyrocarbonate") [67–69] can be used as substitutes for phosgene to synthesize isocyanates from amines. Because of their lack of industrial importance in commodity isocyanate production, the synthesis and utilization of diphosgene [70], triphosgene [71], [72], and pyrocarbonate [73], [74] are not discussed here. However, since the phosgene oligomers still have the potential to liberate phosgene, they should not be regarded as true phosgene substitutes.

In recent years several methods have been developed or investigated for the industrial production of isocyanates that do not require the use of the highly toxic phosgene. The most promising approaches are depicted in Figure 2 together with the classical phosgenation route (path 1):

- Reductive carbonylation of nitro compounds (paths 2 and 3) [75–78]
- Dehydrogenation/degradation of formamides (paths 4 and 5) [79], [80]
- Carboalkoxylation/carboaroxylation of amines (path 6) [81]
- Oxidative carbonylation of amines (path 7) [82], [83]
- Cleavage/thermolysis of carbamates (path 8)

The most important aliphatic diisocyanates, HDI and IPDI, could be manufactured without phosgene by the urea route (see Fig. 2, paths 6 and 8) [84–89].

Reductive carbonylation of nitro compounds, especially nitroaromatic compounds, was the subject of thorough industrial research from

1962 until the early 1990s due to the demand at that time for a new, phosgene-free method for the production of isocyanates and the discussions on the chlorine cycle in industry. The target was a low-cost one-step synthesis starting from the corresponding nitro precursors (Fig. 2, path 2). Arising problems favored an alternative two-step reaction via urethanes (see Fig. 2, paths 3 and 8), which seemed to represent a feasible technical method to significantly reduce the costs of isocyanate production. All announcements referring thereto have been shown to be invalid, simply because the abundant observations claimed in numerous patents and other publications led to an inadequate and optimistic evaluation, although the chemistry was very poorly understood at that time. After 1969 research on homogeneous reductive carbonylation of nitro compounds with compounds of ruthenium, rhodium, and palladium as catalysts increased in academic laboratories. The most recent period is characterized by in-depth studies in academia on the mechanism of activation and catalysis and the nature of the catalytic species, and a declining interest in industry, at least with regard to large-scale manufacture of diisocyanates typically used in the polyurethane industry [75], [76].

Figure 2. Non-phosgene routes to isocyanates in comparison to classic phosgenation route (path 1)

The route to PMDI starting with nitrobenzene has the additional complication that unreactive methyl phenylcarbamate has to undergo the condensation reaction with formaldehyde. Another process for PMDI manufacture is based on the reaction of aniline (or oligomeric amines derived from aniline) and formaldehyde with dimethyl carbonate [90], or with methanol, carbon monoxide, and oxygen [91], [92]. These processes also involve thermolysis of the methyl carbamates as the final step (Fig. 2, path 8). Reaction with unconverted carbamate cannot be prevented because the reactive isocyanates are formed at high temperature. Carbodiimides are also formed as byproducts.

Enichem recently announced that a pilot plant was planned for the phosgene-free two-step manufacture of TDI from TDA using dimethyl carbonate (DMC) to catalytically produce the urethane at 160 – 170 °C (100 % conversion of TDA, 95 % selectivity for urethane), followed by cracking of the urethane in the gas phase at 400 – 450 °C (Fig. 2, paths 6 and 8). It was possible to achieve high conversions of urethane, and all of the methanol could be recycled [93], [94]. ICI disclosed a process in which organic isocyanates (e.g., TDI) were prepared via the corresponding carbamates in high yield and selectivity by treating an amine (e.g., TDA) with DMC in the presence of a catalyst (e.g., lead octanoate) and an organic solvent (chlorobenzene) [95]. High yield and selectivity of the reaction of amines with organic carbonates in the presence of a metal alkanoate catalyst (Ti, Zr, Mn, Fe, Co, Ni, Cu, Zn, Sn, Pb, Bi, Cd) were achieved if the reaction was carried out with DMC, e.g., in the presence of a lead 2-ethylhexanoate catalyst, producing 2,4-bis(methoxycarbonylamino)toluene (2,4-TDU) from TDA [96]. The dicarbamate of bis(1,1,1,3,3,3-hexafluoropropyl) carbonate and MDA could also be prepared in high yield and selectivity. The carbamate could be readily thermolyzed into the corresponding isocyanate MDI [97].

Insufficient overall yield or selectivity was the key problem of the carboalkoxylation/carboaroxylation pathway in the past. Recent developments may have overcome these disadvantages. The only remaining roadblock may be the availability of the necessary carbonates at attractive prices, especially if made without the use of phosgene.

Cytec produces tetramethylxylylene diisocyanate (*m*-TMXDI) by addition of cyanic

acid and hydrogen chloride to 4- or 3-diisopropenylbenzene (Eq. 28) [98].

In the second step of this reaction, carbamic acid chloride (H_2NCOCl) is formed as a byproduct and reacts with diisopropenylbenzene to form the intermediate dichloride and simultaneously regenerate isocyanic acid. The isocyanic acid required is produced in situ by air oxidation of hydrocyanic acid [99].

(28)

Du Pont has developed a process for the production of methyl isocyanate based on the oxidative dehydrogenation of *N*-methylformamide (Fig. 2, path 4) [79], [80], but examples referring to commercially important isocyanates making use of this route are rare and show very small overall yields.

To the present day non-phosgene routes developed for TDI and MDI/PMDI have not been adopted commercially, because the manufacture of difunctional aromatic isocyanates still suffers from the formation of nonvaluable residual byproducts, insufficient catalyst stability, selectivity, efficiency and recovery that rendered the alternative processes economically unacceptable. Nevertheless, attempts are still underway to find routes to diisocyanates that are not based on phosgene.

5. Environmentgal Protection

Hydrogen chloride, the byproduct in the production of organic isocyanates, is part of the chlorine cycle in the chemical industry. In modern phosgenation plants all of the hydrogen chloride produced is separated from excess phosgene and solvent and generally passed on to neighboring plants or companies via pipeline which oxidize the hydrogen chloride to chlorine by electrolysis. The chlorine is reused in the production of phosgene, and total HCl recycling thus results. The alternative method is manufacturing with an external supply of chlorine and HCl delivery to an 1,2-dichloroethane/PVC producer. A third option is to absorb the hydrogen chloride gas in water and selling the acid or using it in another process.

Excess phosgene from isocyanate production is separated from hydrogen chloride and recycled. Ammonia or sodium hydroxide scrubbers are available in the case of accidental phosgene release.

The inert solvents used in the production of organic isocyanates are removed by distillation and recycled. Distillation residues and preliminary cuts containing volatile impurities are incinerated. In particular, trace amounts of the volatile phenyl isocyanate formed in MDI production, resulting from trace amounts of aniline in the starting amines, must be removed because phenyl isocyanate is a strong lacrimator.

6. Quality Specifications and Analysis

The use of organic isocyanates as monomers and as intermediates for pharmaceutical and agricultural chemicals requires a high degree of purity. This is usually achieved by fractional distillation. Solid isocyanates are sometimes purified by crystallization or sublimation.

Polymeric MDI (PMDI) is an undistilled (liquid) product. The composition of PMDI varies, the main component being 40 – 60 % 4,4′-MDI; the remainder is composed of other isomers of MDI, triisocyanates, and higher molecular mass oligomers. Important product variables are functionality and acidity. The 4,4′-MDI content varies because some of this coproduct is removed and sold separately, depending on market demand. Samples containing higher amounts of 2,4′-MDI are also produced for specialty elastomer applications. TDI is produced mainly as an 80:20 mixture of the 2,4 and 2,6 isomers. Pure 2,4-TDI and a 65:35 mixture of 2,4- and 2,6-TDI are also available after multiple crystallization steps.

The commodity isocyanates TDI and MDI are required in high quality by the polymer industry. Several phosgenation byproducts are sources of acidic or hydrolyzable chlorine, which strongly influences the catalytic generation of polyurethane foam. Organic isocyanates are usually characterized by their NCO content, determined analytically by reaction of a sample of the isocyanate with excess di-*n*-butylamine in an inert solvent. Unconverted amine is determined by back titration with hydrochloric acid [9]. Total and hydrolyzable chlorides are determined for all isocyanates. Traces of metals such as iron, tin, and zinc, which act as catalysts in polyurethane reactions, are determined by AAS. GC, HPLC, FTIR, and NMR techniques are also used to determine isomer distribution in TDI, MDI, and H_{12}MDI, and to determine the composition of PMDI. Analytical methods used in the determination of organic isocyanates and derived polyurethanes are summarized in [9].

7. Storage and Transportation

The highly reactive organic isocyanates are hazardous materials, and handling of these chemicals is regulated in all industrial countries. Some crystallization of 4,4′-MDI from PMDI may occur on prolonged storage at low temperature. The same is true for the hydrogenated derivative due to separation of solid *trans,trans*-H_{12}MDI. Exposure to atmospheric moisture must be prevented. The reaction of isocyanates with water leads to the formation of carbon dioxide, which results in a build-up of pressure and the formation of urea. The disaster in Bhopal, India, involving massive release of highly volatile and toxic methyl isocyanate was caused by the addition of water to the methyl isocyanate storage tank [101].

Isocyanates can undergo slow cyclodimerization on storage [14]. To minimize dimerization MDI, for example, must be stored under refrigeration. The formation of dimers in MDI causes turbidity on melting. Specific storage recommendations for individual isocyanates are available from the producers. Thermal degradation of isocyanates occurs on heating. This reaction is exothermic, and above 175 °C a runaway reaction can occur with charring and evolution of carbon dioxide. In view of the heat sensitivity of isocyanates, solid isocyanates such as MDI should be melted with caution following the supplier's recommendations. Isocyanates are also flammable and their vapors are toxic (see Chap. 10).

Isocyanates are transported in railroad tank cars, tank trucks, tanks in ships, containers, and drums. They are stored in steel tanks and processed in steel equipment. For long-term storage stainless steel is recommended. To avoid contamination by atmospheric moisture, a dry air or inert gas blanket is essential.

Decontamination of spilled isocyanates and disposal of isocyanate waste are best conducted by using aqueous ammonia (3 – 8 % concentrated ammonia solution in 90 – 95 % water with 0.2 – 5 % liquid detergent) or aqueous sodium carbonate (5 – 10 % sodium carbonate in 90 – 95 % water and 0.2 – 5 % liquid detergent). An alcoholic solution (50 % ethanol, isopropyl alcohol, or butanol; 45 % water; and 5 % concentrated ammonia) may be preferred because of the low miscibility of isocyanates with water.

8. Uses [7], [8]

Monofunctional organic isocyanates (e.g., methyl, *n*-butyl, phenyl, and halogenated phenyl isocyanates) are used as intermediates in the production of carbamate and urea insecticides and fungicides. *n*-Butyl isocyanate is also employed in the manufacture of sulfonyl urea antidiabetic drugs. Arenesulfonyl isocyanates are used in the production of sulfonylurea herbicides and as drying agents for coating systems.

Di- and polyfunctional isocyanates are used as monomers for addition and condensation polymers. For example, the major consumption of the aromatic isocyanates TDI, MDI, and PMDI is in the production of polyurethanes. Water-blown flexible polyurethane foams are produced from TDI and trifunctional polyols; rigid polyurethane and polyisocyanurate foams are made from PMDI and polyester polyols. The open-cell flexible foams are used mainly in bedding and seating; the closed-cell rigid foams are used as insulation in building and construction. Also PMDI is used as a wood chip binder for particle board, and the coproduct MDI is used as a monomer in the production

Table 4. Worldwide TDI and MDI nameplate production capacity (1999/2000) in 10^3 t/a. The total worldwide production capacity of aliphatic diisocyanates and derivatives thereof in 1999/2000 was estimated at 110×10^3 t/a.

of linear thermoplastic and cross-linked thermoset polyurethane elastomers, primarily in the automotive industry. To achieve faster reaction rates and better green strength in reaction injection molding (RIM), aromatic diamine extenders are used to produce polyurethane elastomers. Amine-terminated polyethers have also been used as comonomers to yield polyureas. Spandex-type elastomeric fibers are made from MDI. The aliphatic diisocyanates HDI, IPDI, and H_{12}MDI are used in the formulation of light-stable polyurethane coatings.

Diisocyanates are often used in modified form. In reaction injection molding, liquid diisocyanates are preferred. Liquid modified MDI is made by conversion of some isocyanate groups to carbodiimide groups [44]. The latter undergo cycloaddition with unconverted MDI to form a cycloadduct (Eq. 29). The small amount of cycloadduct depresses the melting point of MDI to give a product that is liquid at room temperature. The cycloadduct dissociates at elevated temperature, thereby maintaining difunctionality in most applications.

(29)

9. Economic Aspects

Bayer, Pronor, and SNPE/Tolochimie have a pre-eminent position in the monoisocyanates business (Table 1).

The most important aromatic and aliphatic di- or polyisocyanates are listed in Table 2 and Table 3.

Selected MDI and TDI production capacities in 1999/2000 are given in Table 4.

Organic isocyanates are sold by their chemical names or under trade names. The latter are used mainly for the commodity isocyanates. Formulated products and systems containing isocyanates are also sold under a variety of trade names. Some trade names of isocyanates and formulated isocyanates are listed in Table 5.

Table 5. Selected trade names of isocyanates (and/or modifications) for PUR

Trade Name	Producer/Supplier	Product
Basonate	BASF	HDI
Bayhydur	Bayer	HDI (water dispersible polyisocyanate)
Caradate	Bayer-Shell Isocyanates	TDI, MDI – PMDI
Coronate	Nippon PU	TDI, MDI – PMDI
Cosmonate	Mitsui Chem.	TDI, MDI – PMDI, NDI, NBDI
Desmodur	Bayer	TDI, MDI – PMDI, HDI, IPDI, H_{12}MDI, NDI
Enimont	EniChem	MDI – PMDI
Isonate	Dow	TDI, MDI
Lupranat/e	BASF	TDI, MDI – PMDI
Luxate	Lyondell	HDI, IPDI
Millionate	Nippon PU	TDI, MDI – PMDI
Mondur	Bayer	TDI, MDI – PMDI, NDI
PAPI	Dow	PMDI
Rhodocat	Rhodia	HDI (water dispersible polyisocyanate)
Rubinate	Huntsman	MDI – PMDI
Scuranate	Lyondell	TDI
Sumidur	Sumitomo	TDI, MDI – PMDI
Suprasec	Huntsman	MDI – PMDI
Takenate	Takeda	TDI
Tedimon	EniChem	TDI
Tectrade	Huntsman	MDI – PMDI
Tolonate	Rhodia	HDI, IPDI
Vestanat/e	Degussa	IPDI
Voranate	Dow	TDI, MDI – PMDI

In 1998 the worldwide consumption of plastics was estimated at 150×10^6 t/a, of which PU-based materials accounted for ca. 5 % (7.5×10^6t/a). About 30 % of PU was used in the area of furniture/mattresses; automotive and construction applications accounted for 15 % each. Technical insulations accounted for 10 %. The remaining 30 % was divided between coatings, adhesives, TPU, shoes, artificial leather, elastomers, fibers, integral-skin foams, and electronic encapsulation. 80 % of all PU materials could be classified as foam (flexible, rigid, and semi-rigid integral-skin). Total consumption of diisocyanates in 2000 exceeded 3.4×10^6 t (Table 6). The average global growth rate was expected to be ca. 5 % for the PU raw materials TDI, MDI, and polyols.

After years of providing polyurethane precursor materials such as MDI, TDI, or polyols, polyurethane producers appear to be moving towards becoming fully integrated polyurethane providers, with acquisition of ICI's urethane business by Huntsman and, more recently, Bayer's acquisition of Lyondell's polyols business. The companies are making their moves as the polyurethane industry undergoes an extended period of growth [102].

Table 6. Regional demand for the diisocyanates TDI and MDI (1999) in10^3 t/a. (Source: International Isocyanate Institute statistics, May, 2000).

Region	TDI	MDI
NAFTA	335	764
Europe	298	854
Japan	75	165
Asia-Pacific (without Japan)	323	340
Latin America	110	58
Rest of the World	121	84
Total demand	1262	2265
Total consumption	1333[a]	2309[a]

10. Toxicology and Occupational Health

Isocyanates are classified as dangerous substances (EC Guidelines). Both monomeric and polymeric MDI are labeled "harmful", TDI is labeled "very toxic", most others are labeled "toxic" and should therefore be handled with care.

All diisocyanates are very reactive chemicals that are potentially hazardous to humans. They are harmful by inhalation of vapors and aerosol mists, irritating to eyes, respiratory system, and skin, and some may cause sensitization by inhalation and skin contact. The potential for exposure depends on the vapor pressure.

Table 7. Acute toxicity of diisocyanates in rats (according to MSDS)

Isocyanate	Type	LD_{50} (oral), mg/kg	LC_{50} (inhalation), mg/m^3	Concentration of saturated vapor in air at 25 °C, mg/m^3	Maximum allowable concentration, mg/m^3
HDI	1,6-HDI monomer	746	120 – 350[a]	95	0.035
IPDI	monomer	5490	40[b]	3.65[c]	0.09
H_{12}MDI	4,4'-H_{12}MDI monomer	>11 000 (>10 000[d])	434[b]	0.22	0.054
TDI	TDI-80	5800	610[e]	255	0.07
MDI-PMDI	4,4'-MDI monomer	>2500	490[b]	0.09	0.05
NDI	1,5-NDI	>15 000	>2075[f]		0.09

[a] 4-h exposure. [b] Aerosol, 4-h exposure. [c] 20 °C. [d] LD_{50} (dermal), rabbit. [e] Aerosol, 1-h exposure. [f] 1-h exposure.

Volatile short-chain monomeric aliphatic isocyanates (e.g., methyl isocyanate) must be handled with particular caution. The more volatile isocyanates are strong lachrymators, but their primary physiological effect is respiratory irritation [103]. Therefore isocyanates must be handled with procedures designed to minimize exposure.

For TDI, OSHA has set a PEL of 0.02 ppm as a ceiling concentration and a STEL of 0.02 ppm as a 15-min TWA. For MDI, OSHA guidelines are a PEL of 0.02 ppm as a ceiling concentration. Up to late 1998, OSHA guidelines have not been established for major aliphatic diisocyanates (HDI, IPDI, H_{12}MDI) [104]. Data on the acute toxicity of several diisocyanates are listed in Table 7.

There are contradictory results on the mutagenicity of TDI and MDI. According to the Salmonella/microsome test [105] in a suitable matrix for isocyanates, MDI gives negative findings while TDI gives positive findings due to the instability of TDI leading to TDA, a known mutagen [106].

1. Introduction

Isoprene [*78-79-5*] (**1**), C_5H_8, M_r 68.118, is named according to IUPAC rules as 2-methyl-1,3-butadiene. Its isomers include the commercially less important compounds *cis*- and *trans*-1,3-pentadiene (**2**) [*504-60-9*] (piperylene).

1

2

Free isoprene has been observed in nature only in very low concentration [1], [2]. The compound is present in roasted coffee and in the gas phase of tobacco smoke [3], and can be regarded as a precursor of polycyclic aromatics [4]. Isoprene is the structural unit of countless natural products (the terpenes, which include natural rubber and camphor) as well as biologically important substances such as vitamin A and the steroid sex hormones (cf. the "isoprene rule" of O. Wallach and L. Ruzicka [5]). It is now known, however, that the biosynthesis of rubber and other natural products containing the isoprene skeleton proceeds not via isoprene itself, but rather via mevalonic acid [*150-97-0*] (**3**), 3,5-dihydroxy-3-methylpentanoic acid [6].

3

Isoprene was first synthesized in 1860 by C. E. Williams by the pyrolysis of natural rubber [7]. The reverse reaction–polymerization of isoprene to poly(*cis*-1,4-isoprene), with a structure corresponding to that of natural rubber–was long the subject of intensive effort [8]. The first successful attempts were reported in 1954 and 1955 by the Goodrich Gulf (Al–Ti Ziegler catalyst [9]) and Firestone companies (alkyl lithium catalyst [10]).

Isoprene was commonly prepared on a laboratory scale by thermolysis of turpentine oil (the so-called isoprene lamp of C. Harries [11]). Pyrolysis of dipentene [*5989-27-5*], limonene, was even used in the United States early in the Second World War as a commercial source of isoprene (Bibb process [12]). The reverse of this reaction–synthesis of terpenes from isoprene–has been discussed in a vast number of scientific publications, but has so far achieved little commercial significance.

Isoprene itself was commercially unimportant until after the Second World War because it could not be offered at a price that was sufficiently attractive for its principal potential market, the manufacture of synthetic rubber. This situation changed with the development of improved methods for obtaining isoprene from petrochemical sources, as well as of polymerization techniques for the generation of poly(*cis*-1,4-isoprene), a synthetic rubber whose valuable material characteristics have been widely confirmed.

Spectra are to be found in the literature: IR [16], UV [17], NMR [18], Raman [19].

The *solubility* of isoprene in water at 20 °C is 0.029 mol%. It is miscible in all proportions with organic solvents such as ethanol, diethyl ether, acetone, and benzene. Regarding solubility in high-boiling, polar solvents, see chap.4. The Bunsen absorption coefficient α for oxygen in isoprene is 0.4065 m^3 m^{-3} $mbar^{-1}$ at 0 °C and 0.4557 at 20 °C.

Binary *azeotropic mixtures* of isoprene are listed in Table 1. The azeotrope of isoprene with *n*-pentane has acquired commercial significance in the isolation of pure isoprene . For information regarding ternary azeotropes of isoprene see [19].

Table 1. Binary azeotropes of isoprene [19]

Component	*bp*, °C	Isoprene content, wt %
Methanol	29.57	94.8
n-Pentane	33.6	72.5
Carbon disulfide	<34.15	<93

Acetonitrile	33.5 – 33.6	97.5
Isopropylamine		>72.4

Data for vapor – liquid equilibria of binary and ternary mixtures of isoprene and other organic compounds are provided in [20] and [21]. Liquid – liquid equilibrium data for binary and multicomponent systems containing isoprene are listed in [22]. Activity coefficients at infinite dilution are given in [23]. Curves describing the temperature dependence of various physical quantities may be found in [24] and [25].

Chemical Properties. Spectroscopic analysis has revealed that most isoprene molecules in the ground state at 50 °C are in the *s-trans* conformation. Only 15 % of the material has the *s-cis* form, which is higher in energy by 6.3 kJ/mol.

Equilibrium concentrations for the isomer system isoprene – pentadiene (a total of seven isomers) are presented graphically in [26] for temperatures between 200 and 1600 K. Reaction enthalpies for the corresponding isomerizations are provided in [27].

Isoprene exhibits the typical characteristics of a conjugated diene. Its methyl group makes the compound react more readily than butadiene with electrophiles and Diels – Alder dienophiles. Moreover, the reactivity of isoprene is more varied than that of butadiene, which only possesses two types of hydrogen atoms in contrast to the four of isoprene. Isoprene can participate in a wide range of reactions (including substitution, addition, ring formation, complexation, and telomerization reactions). For a summary of the general reactivity of isoprene see [19].

The only chemical reaction of isoprene of practical importance is its conversion to terpenes. Isoprene is mainly used for polymer synthesis (Chap. 6).

3. Production

3.1. Synthetic Methods

Laboratory methods for the synthesis of isoprene from a wide variety of starting materials are summarized in [19].

Industrial syntheses of isoprene utilize the following four principles in creating the C_5 skeleton:

$C_1 + C_4 \longrightarrow C_5$
$C_2 + C_3 \longrightarrow C_5$
$C_3 + C_3 \longrightarrow C_6 \longrightarrow C_5 + C_1$
$C_4 + C_4 \longrightarrow C_8 \longrightarrow C_5 + C_3$

$C_1 + C_4 \longrightarrow C_5$. *Isobutene* [*115-11-7*] is the C_4 building block in several syntheses of this type (Fig. 1). The C_1 component may be formaldehyde [*50-00-0*] (reactions 1, 2, and 3 in Fig. 1), one of its derivatives, or methanol [*67-56-1*] [28]. The C_1 molecule carbon monoxide also plays a role in synthesis; this route (4 in Fig. 1) involves hydroformylation of isobutene to 3-methylbutanal [30].

The most frequently used synthetic procedure is the acid-catalyzed addition of formaldehyde to isobutene (Prins reaction, route 1 in Fig. 1). This produces a 1,3-dioxane, which is then cleaved in the gas phase (at 200 – 300 °C) over an acid catalyst (e.g., H_3PO_4 on a suitable carrier) to give isoprene, with recovery of half of the reacted formaldehyde. This reaction was first suggested for the synthesis of isoprene in 1938 [31], and it became widely known through the work of the Institut Français Pétrol [32], [33]. The method became the subject of further development at several locations as a result of the ready availability of the starting materials [34–36]. Individual procedures differ primarily in terms of catalysts employed and engineering details. Production facilities of this type are currently in operation in Japan (cf. Chap. 7).

The ultimate goal of developmental efforts in the synthesis of isoprene from isobutene and formaldehyde has been simplification and increased competitiveness. Takeda Chemical in Japan has proposed a one-step gas-phase procedure (cf. Fig. 1, route 2), in which isobutene and formaldehyde are passed over oxide catalysts at 300 °C [36]. Much preliminary work toward this approach was contributed by British Hydrocarbon Chemicals.

An important aspect of the above syntheses with respect to their economic viability is the problem of byproduct formation from formaldehyde. Efforts have therefore been made to use formaldehyde derivatives as a way of suppressing resin buildup. For example, both Idemitsu and Sun Oil have suggested the use of methylal [*109-87-5*] (**4**), dimethoxymethane [37], [38]. Marathon Oil has proposed a two-step process based on monochlorodimethyl ether [*107-30-2*] (**5**) [39], [40], while Sumitomo has discussed the use of dioxolane [*646-06-0*] (**6**), 1,3-dioxacyclopentane [41].

4

5

6

Consideration has also been given to integrating formaldehyde production directly into the process, i.e., by mixing methanol and oxygen directly with isobutene [42]; a modification of this approach is the use of methyl *tert*-butyl ether (MTBE) and oxygen [43].

Japanese patent applications from Kuraray, Nippon Zeon, and Sumitomo Chemical use *tert*-

Figure 1. Synthesis of isoprene from isobutene

butyl alcohol [*75-65-0*] as a C_4 building block in isoprene synthesis, while a number of former Soviet publications describe a variety of methods based on cleavage of 1,3-dioxane. Probably the greatest disadvantage of the one-step gas-phase process is the low space – time yield of the catalysts, together with their rapid deactivation under the prevailing reaction conditions [44–46]. It is not known whether any of the above-described variants have been carried to production scale.

In addition to the Prins reaction with all its modifications, there is one other economically interesting route to the synthesis of isoprene from isobutene and formaldehyde via 2-methyl-1-buten-4-ol (**7**) (Fig. 1, reaction 3) [47]:

One advantage here is that the synthesis (ene reaction) of the intermediate **7** is a purely thermal process occurring in the liquid phase, which permits use of an aqueous formaldehyde solution [48]. Dehydration of **7** is conducted in aqueous NaCl/HCl solution [49] that can be easily regenerated (low catalyst cost).

2-Butene [*107-01-7*] is the C_4 building block for an entirely different synthesis of isoprene based on the $C_1 + C_4 \rightarrow C_5$ principle via the intermediate 2-methylbutanal [*96-17-3*] (Fig. 2). 2-Methylbutanal is readily prepared by rhodium-catalyzed hydroformylation of 2-butene [30], [50], [51]. An alternative route to this C_5 aldehyde is the catalytic hydrogenation of 2-ethylacrolein which is easily prepared from *n*-butyraldehyde and formaldehyde [52], [62].

Figure 2. Synthesis of isoprene via 2-methylbutanal.

Catalytic dehydration of 2-methylbutanal to isoprene has been the subject of numerous studies [53]. A patent issued to Erdölchemie [54] describes the use of a β-phosphate catalyst, which is also discussed in most of the subsequent publications dealing with this reaction [30], [50], [55–57]. Other patents for the dehy-

dration of 2-methylbutanal describe the use of magnesium ammonium phosphate [58], molecular sieve [59], as well as zeolite catalysts [60]. Nevertheless, all the catalysts cited are subject to rapid loss of activity [30], or else display low activity from the outset. Zeolites that have been silanized or doped with small amounts of cesium display longer lifetimes. For example, a zeolite containing 0.4 % cesium showed no decrease in yield (51 %) or isoprene selectivity (88 %) after 120 h of use [61].

Cleavage of 3-methylbutanal over a boron phosphate catalyst (Fig. 1, route 4) gave poorer results than were observed with the 2-isomer [30], [62]. At the present time there are still no industrial facilities for the synthesis of isoprene from *n*-butenes or butanal via 2-methylbutanal.

$C_2 + C_3 \longrightarrow C_5$. Codimerization of ethylene and propene in the presence of triethylaluminum leads to 2-methyl-1-butene, which can be dehydrogenated to isoprene. However, this method has not been carried beyond the experimental stage [63], [64].

By contrast, another isoprene synthesis based on C_2 and C_3 starting materials (acetylene and acetone) was carried to production scale by SNAM in Italy, whose manufacturing facilities in Ravenna had been in operation for several years [65–68]; the plant is, however, not currently in operation. A plant based on this principle has been built in the Republic of South Africa (see Chap. 7). The isoprene produced by this method is extremely pure but the process is relatively expensive.

$C_3 + C_3 \longrightarrow C_6 \longrightarrow C_5 + C_1$. The first step of the familiar Goodyear – Scientific Design isoprene synthesis consists of the dimerization of propene to 2-methyl-1-pentene. This is then isomerized to 2-methyl-2-pentene, which is subsequently cracked with loss of methane to give isoprene [64], [69], [70].

The first commercial synthesis of isoprene was based upon this principle (Beaumont, Texas). Production was discontinued after a fire in 1975 because it was no longer competitive due to sharp increases in the price of propene.

$C_4 + C_4 \longrightarrow C_8 \longrightarrow C_5 + C_3$. Olefin metathesis represents a very interesting approach to isoprene manufacture from readily available petrochemicals. Thus, a butene fraction containing 2-butene and isobutene yields 2-methyl-2-butene and propene:

2-Methyl-2-butene can then be dehydrogenated to isoprene by standard methods (cf. Section 3.2) [71–75]. However, one disadvantage of the metathesis reaction is that all of the olefins in the reactor can react with one another yielding a broad spectrum of byproducts. This is especially true if the starting material is a technical-grade butene mixture containing 1-butene, which represents the only economically feasible starting material [76].

3.2. Dehydrogenation Procedures

The production of isoprene by dehydrogenation of isopentane or the isopentenes (methyl-

butenes) has been the subject of many investigations [77], [78]. Such reactions closely resemble the analogous dehydrogenations of *n*-butane and the *n*-butenes to butadiene (→ Butadiene, Chap. 4.1.).

One-step dehydrogenation of isopentane to isoprene can be carried out according to the Houdry – Catadiene procedure (Cr_2O_3/Al_2O_3 catalyst, ca. 600 °C, and ca. 7 kPa) with a yield of 52 % [79–81]. Isoprene is prepared commercially in this way in the former Soviet Union [82]. A two-step process for the dehydrogenation of isopentane is described in [83].

Isoprene production plants based on the dehydrogenation of methylbutenes exist in the United States and the Netherlands but are not currently in operation. The requisite starting material comes largely from cat-cracker off-gases [84], [85]. Methylbutenes are extracted in the form of semiesters from the appropriate distillation fraction of these off-gases by dissolution in sulfuric acid, followed by back extraction with paraffinic hydrocarbons (Sinclair procedure). As far as is known, dehydrogenation is effected with a Shell catalyst (Fe_2O_3– K_2CO_3– Cr_2O_3) at 600 °C and dilution of the methylbutenes with steam; the yield is 85 % [86]. A Sr – Ni – phosphate catalyst (Dow Type S catalyst, a modification of the well-known Dow Type B catalyst) has also been reported to be suitable for this reaction [87].

Oxidative dehydrogenation of isopentane [88–90] and the methylbutenes [91–95] has also been widely investigated. The behavior of oxide catalysts in the oxidative dehydrogenation of the methylbutenes is described in [45]. The yield and selectivity for isoprene are reported to be 60 % and 95 %, respectively.

Although many publications and patents discuss the preparation of isoprene by dehydrogenation, little significant progress is apparent. Two former Soviet reports will be mentioned as examples. The oxidative dehydrogenation of methylbutenes to isoprene with aluminum phosphate catalysts is described in [96]; the reactivity of the olefins decreases in the order 3-methyl-1-butene, 2-methyl-2-butene, and 2-methyl-1-butene. Oxidative dehydrogenation of methylbutenes to isoprene can also be achieved with a silicate catalyst doped with alkaline-earth oxides or the oxides of nickel, iron, or cobalt [97].

Conversion of isopentane and methylbutenes to isoprene by co-oxidation is claimed in [98].

3.3. Recovery from C_5 Cracking Fractions

The C_5 cracking fractions obtained as a byproduct in the pyrolysis of hydrocarbons to ethylene (→ Ethylene) have come to play a major role in isoprene manufacture [99]. Workup of the cracking products from naphtha cleavage yields so-called " crack gasoline", which contains only low concentrations of isoprene and other C_5 hydrocarbons, the major constituents being C_6– C_8 aromatics. Nevertheless, this material may still be distilled into C_5 and aromatic fractions.

Figure 3. Influence of cracking severity on the product distribution [102]
a) Ethylene; b) Propene; c) Benzene; d) Butadiene; e) Toluene; f) Cyclopentadiene; g) Isobutene; h) Isoprene; i) Piperylenes

The yield of isoprene is typically 2 – 5 wt % based on ethylene, although it may be increased by starting with a heavier raw material such as gas oil. Table 2 demonstrates the influence of the nature of the cracker feed on the C_5 product distribution. Figure 3 shows that the yield of isoprene decreases with increasing crack severity

Table 2. Composition (in weight percent) of the C_5 fraction from the pyrolysis of hydrocarbons [100] and boiling points of the individual components

Component	*bp* at 101.3 kPa, °C	Starting material					
		1	2	3	4	5	6
Isopentane	27.85	1.99	11.02	0.99	24.1	7.8	0.8

Cyclopentadiene	42.50	16.46	2.40	17.77	7.5	20.4	37.0
Cyclopentene	44.24	12.50	5.76	6.16	1.6	5.9	5.5

1) Paraffin wax (*mp* 43.5 °C). 2) Low octane gasoline (high severity cracking). 3) Sulfur-containing petroleum (high severity cracking). 4) Naphtha. 5) Romaskino straight-run gasoline (boiling range ≈ 40 – 160/180 °C). 6) Synthetic gasoline from Fischer – Tropsch synthesis (boiling range ≈40 – 150 °C).

(temperature and residence time). Nevertheless, this overall decrease is accompanied by an increase in isoprene concentration in the C_5 crack fraction (cf. Table 3). Table 3 also provides the product distribution in a typical methylbutene dehydrogenation fraction. Based on energy consumption, recovery of isoprene from crack fractions is considerably more efficient than synthesizing the compound chemically [101].

Increasingly heavier raw materials will be used in Europe and the United States for ethylene production in crackers [100]. The quantity of the isoprene byproduct will therefore also increase. In some crackers only an aromatic fraction is recovered from crack gasoline. The residue (i.e., the C_5 hydrocarbons) is often combined with the C_4 fraction and recycled with the cracker feed.

Pure isoprene cannot be isolated from the C_5 crack fraction simply by distillation, because the numerous components of the mixture differ only slightly in boiling point (cf. Table 2), and isoprene forms an azeotropic mixture with *n*-pentane (cf. Table 1). For the separation of cyclopentadiene from the C_5 crack fraction by dimerization, see → Cyclopentadiene and Cyclopentene, Chap. 1.3.

Distillative enrichment of isoprene in C_5 fractions to a concentration of 25 – 50 % is of some commercial interest because it reduces the transportation and separation costs associated with the isolation of pure isoprene. Examples of special isoprene enrichment processes are described in [103].

Goodyear has developed a process for separating isoprene from C_5 crack fractions in the form of its azeotrope with *n*-pentane [104], [105]. This procedure was carried to production scale in France, although that facility is no longer in operation. The resulting mixture is free of components that might adversely affect the polymerization of isoprene, and is thus suitable for polymerization processes that employ a solution of isoprene in an inert hydrocarbon.

"Chemical" isolation procedures involving copper(I) compounds have also been considered for the recovery of isoprene from C_5 hydrocarbon mixtures [106]. In contrast to the situation with butadiene (→ Butadiene) this process has never been adopted commercially for isoprene.

Selective organic solvents are used in "physical" processes for separating isoprene by extractive distillation with or without liquid – liquid extraction. The principles involved are similar to

Table 3. Typical composition (in weight percent) of C_5 crack fractions as a function of cracking severity

Component	Crack severity			
	Mild	Normal	Severe	Methylbutene dehydrogenation fractions
Pentanes	26.70	34.36	14.12	65 – 75
n-Pentenes	5.15	6.60	4.21	65 – 75

∗ The figures indicate the ratio of the volatility of the specified hydrocarbon to that of isoprene measured at 50 °C in a mixture containing 12.5 wt % of the hydrocarbon, 12.5 wt % of isoprene, and 75 wt % of solvent.

∗∗ ACN = acetonitrile; DMF = dimethylformamide; NMP = *N*-methylpyrrolidone; MOPN = β-methoxypropionitrile; DMAC = dimethylacetamide; DMSO = dimethyl sulfoxide; γ-BL = γ-butyrolactone

those developed for separation of butadiene from C_4 crack fractions (→ Butadiene, Chap. 4.2.). The most appropriate solvents for production-scale separation of isoprene from other hydrocarbons include *N*-methylpyrrolidone [107], [108], dimethylformamide [109], [110], and acetonitrile [111]. The relative volatilities of the hydrocarbons in various polar solvents (i.e., the selectivities of the solvents for the isolation of isoprene from C_5 hydrocarbon mixtures) are listed in Table 4. Figure 4 shows the relationship between the overall concentration and the relative volatilities of 2-methyl-2-butene – isoprene mixtures in various solvents; these data are of considerable importance for estimating the size of a proposed production facility. 2-Methyl-2-butene is the key low-boiling component under the conditions prevailing in this extractive distillation procedure. Additional data relevant to selective solvents for separation of isoprene are presented in [113]. Isolation of isoprene concentrates from C_5 hydrocarbon mixtures by extrac-

tion with selective organic solvents is discussed in [114].

Figure 4. Relationship between the total concentration and the relative volatilities α_r of 2-methyl-2-butene – isoprene mixtures in various solvents [112]
a) Acetonitrile; b) Dimethylformamide; c) *N*-Methylpyrrolidone; d) β-Methoxypropionitrile; e) Dimethylacetamide; f) Dimethyl sulfoxide; g) γ-Butyrolactone

Figure 5 is a flow diagram for the isolation of isoprene from a C_5 cracking fraction. The first step in the separation is a combination of a liquid – liquid extraction with an extractive distillation, an approach particularly suited to C_5 fractions with a low isoprene concentration. Preconcentration of isoprene occurs in extractor (a). Crude isoprene is removed as a sidestream from the extractive distillation column (b), after which it is freed from piperylenes and cyclopentadiene in a second extractive distillation step incorporating columns (c) and (d). Final purification of isoprene to polymerization grade occurs in distillation columns (e) and (f) [115]. C_5 fractions that contain cyclopentadiene can be used in this process because the cyclopentadiene is removed together with the piperylenes.

Incorporation of relevant equipment in this process allows the isolation of cyclopentadiene or the commercially valuable cyclopentene (→ Cyclopentadiene and Cyclopentene, Chap. 2.3.). Introduction of a supplementary column permits recovery of pure piperylenes.

The high quality specifications that are required for isoprene used in the preparation of poly(*cis*-1,4-isoprene) are met with the aid of modern separation facilities. It should be noted, however, that suggestions have also been made for the chemical removal of specific impurities (e.g., cyclopentadiene, acetylene) [116].

Economic comparison of the various techniques for separating isoprene from C_5 cracking fractions is difficult because a large number of criteria must be considered and each must be assigned a proper weighting which depends on the location of the plant. Various selective solvents are compared in [112] with respect to their suitability for isoprene separation. Energy consumption data are analyzed in [117]. A detailed cost analysis for one specific solvent is provided in [118].

4. Quality Specifications

Isoprene is used primarily for the synthesis of polymers, including poly(*cis*-1,4-isoprene) and block polymers containing styrene (SIS polymers, see Chap. 6) [119].

Table 5 provides typical specifications for isoprene used as a monomer for the production of poly(*cis*-1,4-isoprene). Purity specifications for polymerization with Ziegler catalysts are less rigorous than for polymerization with alkyl lithium catalysts. The latter are also used for preparing SIS polymers.

Table 5. Monomer specifications for isoprene used in the production of poly(*cis*-1,4-isoprene) [120]

Component	Alkyl lithium catalyst	Ziegler catalyst (Al/Ti)
Isoprene, wt %	99.5	99.5
Monoolefins, wt %	0.4	0.5
1,3-Pentadiene, ppm	<80	<200
Cyclopentadiene, ppm	< 1	< 1
Acetylene, ppm	< 3	< 50
Allene, ppm	< 5	< 50
Carbonyl compounds, ppm	< 5	< 10
Sulfur (as H_2S), ppm	< 5	< 5
Water, ppm	< 5	< 5

Isoprene for use as a monomer in the manufacture of butyl rubber (isobutene – isoprene rubber, IIR) may contain higher levels of the common impurities, as indicated in Table 6. Table 6 also contains information about technical-grade isoprene.

In most polymerization processes, isoprene is used in dilution with other inert hydrocarbons.

Figure 5. Recovery of isoprene from C_5 hydrocarbon mixtures by a combination of extraction and extractive distillation [107]
a) Liquid – liquid extraction column; b) – d) Columns for extractive distillation; e) Butyne column; f) Isoprene column; g) Cooler; h) Heat exchanger; i) Reboiler; j) Condenser
—— Vapor phase; —— Liquid phase

In the production of IR and SIS polymers, it may therefore be more economical to use an isoprene product (isoprene concentrate) in which isoprene of the required purity (content of cyclopentadiene, acetylene, etc.) is diluted with hydrocarbons that do not interfere with polymerization. Thus, in the synthesis of isoprene rubber a starting material containing 60 – 85 % isoprene is sufficient, whereas an isoprene content of 80 – 90 % is required for SIS polymers. For the synthesis of butyl rubber, however, the isoprene cannot be diluted with other hydrocarbons.

Table 6. Specifications for technical-grade isoprene [121] and isoprene intended for use in the production of butyl rubber (IIR) [122]

Component	Technical-grade isoprene	Isoprene for IIR
Isoprene, wt %	99	>92
Diolefins (total), wt %		>95
C_3 olefins, wt %	1	
Cyclopentadiene, wt %	0.05	<1
α-Acetylene, wt %		<0.35
Peroxides (as H_2O_2), ppm	100	<10
Carbonyl compounds (as acetone), ppm	150	<500
Sulfur (as H_2S), ppm	5	<100
Distillation residue, wt %		<1.5

The purity of isoprene is normally verified by gas chromatography. Data for sulfur, peroxides, carbonyls, distillation residues, and inhibitors are determined by the usual standard analytical methods, preferably those based on ASTM or ISO/DIN recommendations.

5. Storage and Transportation

Table 7. Dimerization of isoprene as a function of temperature [123]

Temperature, °C	Dimerized isoprene, wt %/h
20	0.000017
40	0.00019
60	0.0021
80	0.023
100	0.25

Appropriate regulations must be observed during construction and operation of tank storage facilities for isoprene (e.g., the VbF rules in the Federal Republic of Germany). Reference [123] should be consulted regarding special problems, such as prevention of the formation of peroxides (→ Butadiene, Chap. 5.). Other conditions being equal, the rate of reaction of oxygen with isoprene is significantly greater than that with butadiene. Data regarding the rate of thermal dimerization of isoprene are given in Table 7; this reaction cannot be suppressed by

inhibitors. Thermal dimerization at low temperature is a Diels – Alder reaction, producing only cyclohexene derivatives, while at higher temperatures cyclooctadienes are also formed [124]. Transport regulations are summarized in Table 8 [125].

Table 8. Guidelines for the labeling and transport of isoprene

Means of transport	Region	Guideline
Road	Europe	ADR class 3, no. 2 a

	International	IMDG Code class 3.1, UN no. 1218
Air freight	International	IATA class 3, UN no. 1218

6. Uses

6.1. Polymer Synthesis

Most of the isoprene that is produced is utilized for the synthesis of poly(*cis*-1,4-isoprene) (isoprene rubber, IR), a material (particularly the titanium type) that closely resembles natural rubber in both structure and properties (→ Rubber,3. Synthetic). This IR is largely used for the production of vehicle tires (→ Tires). By contrast, poly(*trans*-1,4-isoprene) has the properties of guttapercha or balata, and has found no major commercial application. Most of the trans polymer is limited to the manufacture of cable insulation and golf balls [124, p. 499], [126].

The second largest market for isoprene is the manufacture of styrene – isoprene – styrene (SIS) block copolymers (→ Thermoplastic Elastomers) [119], [120, p. 837], [124, p. 532], [127]; 0.79 – 0.88 t of isoprene are required per tonne of polymer. These products are especially useful as thermoplastic rubbers and as pressure-sensitive or thermosetting adhesives.

Smaller amounts of isoprene are used in the production of butyl rubber (isobutene – isoprene rubber, IIR), a copolymerizate with isobutene (→ Rubber,3. Synthetic) [128]. The isoprene content of butyl rubber is 0.5 – 3.0 mol%. The distinctive features of IIR include its low gas permeability, leading to its use in the construction of hoses and as a liner in tubeless tires.

Finally, mention should also be made of the hydrocarbon resins (petroleum resins), which result from the copolymerization of isoprene from cyclopentadiene-free C_5 crack fractions with other unsaturated C_5 compounds (→ Resins, Synthetic) [129].

6.2. Terpene Synthesis

The chemical reactions of isoprene are very varied [19], but they have limited industrial significance. Only terpene synthesis is important and is the subject of intensive investigation.

C_5+C_3+C_2 Routes. In 1972, Rhodia Incorporated (United States) began to develop a route for the industrial synthesis of C_{10} terpenes and their derivatives from isoprene (C_5), acetone (C_3), and acetylene (C_2) (Fig. 6). The isoprene is first reacted with hydrochloric acid to give prenyl chloride which is then converted to dehydrolinalool in two steps [7], [130]. Rhodia used the dehydrolinalool as a starting compound for the industrial synthesis of most of the compounds shown in Figure 6, but the plant was decommissioned. Kuraray in Japan, however, produces the compounds shown in Figure 6, squalane, and other substances from isoprene [131].

C_5+C_5 Routes. Rhodia has also used a *Grignard synthesis* to produce the C_{10} terpene alcohol lavandulol [*1845-51-8*] from two molecules of isoprene [132].

Lavandulol

Isoprene can react in a variety of ways to form terpenes via oligomerization or telomerization (→ Terpenes) [133–137]. The syntheses of myrcene and *N*,*N*-diethylnerylamine (C_{10} terpenes) are described below as examples of

Figure 6. Synthesis of terpenes from isoprene via the $C_5+C_3+C_2$ route

scientifically and industrially important linear oligomerization and telomerization reactions, respectively.

All naturally occurring terpenes are composed of isoprene units arranged in a "head-to-tail" fashion [133–137]. Terpenes synthesized from isoprene must also possess this structure and their double bonds must be correctly positioned [138], [139]. On account of this problem C_{10} terpenes and their derivatives are not generally synthesized from isoprene but by other routes [47], [138].

Variation of the quantitative composition of a Pd-complex catalyst can influence the structure of dimethyloctadienes synthesized from isoprene [140].

Myrcene [*123-35-3*] has been synthesized by *oligomerization* of isoprene with a sodium/dialkylamine catalyst by TAKABE et al. [141] (see also [142–144]).

Myrcene

Nissan Chemical Industries have developed a route for the industrial production of myrcene and have announced that it will be implemented industrially [145].

Telomerization of isoprene proceeds with a variety of compounds, e.g., ammonia or amines [146] (see also [135], [136]). Interestingly, reactions occur in which the regioselectivity can be highly modified by varying the amount and concentration of Brönsted and Lewis acids added to the catalyst [147], [148].

Isoprene can react with diethylamine to form *N,N*-diethylnerylamine [*40137-00-6*] [149]; this telomerization reaction is catalyzed by butyl lithium. *N,N*-Diethylnerylamine can be further reacted to give linalool, geraniol, nerol, hydroxycitronellal, citronellal, and menthol (Fig. 7) [149–152].

The Takasago Perfumery Company in Japan has developed an industrial synthesis for enantiomerically pure L-menthol [*2216-51-5*] from optically active citronellal. The reaction involves the asymmetric allylamine – enamine isomerization of *N,N*-diethylgeranylamine or *N,N*-diethylnerylamine with a Rh – BINAP [2,2′-bis(diphenylphosphino)-1,1′-binaphthyl] catalyst [153–156]. Geranylamine is obtained by addition of diethylamine to myrcene [22]. The synthesis of nerylamine is described above [149]. Takasago produces 1500 t/a of L-menthol by this route.

Figure 7. Synthesis of terpenes from isoprene via nerylamine

7. Economic Aspects

Isoprene is used mainly as a starting material for the manufacture of synthetic rubber, the market for the compound therefore depends heavily upon the widely varying price of natural rubber (cf. [157] and corresponding publications from previous years). As noted in Section 3.3, extraction from C_5 crack fractions is the most economical route to isoprene [101]. Nevertheless, a key factor in the calculation is the location of the separation facility, since separation is only profitable if C_5 fractions (possibly enriched in isoprene) from several cracking plants can be transported economically to a separator of sufficient capacity [158]. Utilization of the large quantities of residual C_5 hydrocarbons is also a major consideration.

The total production of C_5 diolefins in Western Europe in 1987 was 83 000 t [159]. It is of some interest that more (dimeric) cyclopentadiene was produced (44 000 t) than isoprene (23 000 t). The remainder (15 000 t) was accounted for by piperylenes. As shown in Figure 8, an increasing demand for cyclopentadiene relative to isoprene is also anticipated in the

United States in the coming years. The growing interest in cyclopentadiene may be attributed to the latest developments in the field of metathetic polymerization of the compound [161]. Combining this technology with the reaction injection molding method opens the way to very economical injection castings with good mechanical properties.

Figure 8. Estimated demand for C_5 dienes in the United States [160]

Table 9 provides an overview of the known production facilities for pure isoprene and isoprene concentrates. The isoprene concentrates are used either directly or, if necessary, after additional purification. Table 10 summarizes production capacities and actual production of polyisoprene (IR), butyl rubber (IIR), and synthetic rubber for the years 1987 and 1989, subdivided according to country. Corresponding totals for the period 1979 – 1989 are given in Table 11. The obvious decrease in the production of polyisoprene is largely a result of declines in the United States. Consumption data for isoprene used in the manufacture of SIS copolymers in 1986 follow [119]:

United States 25 000 t
Western Europe18 000 t
Japan 250 t

8. Toxicity and Occupational Health

Acute Toxicity. At high levels of exposure isoprene is an anesthetic in animals, finally resulting in paralysis and death. Single 2-h inhalation exposures of mice to 56 000 mg isoprene per cubic meter of air did not produce toxic effects. Levels of 98 000 – 126 000 mg/m^3 resulted in deep narcosis; death occurred after 2 h of exposure to 140 000 mg/m^3. The LC_{50} for a 2-h exposure was 180 000 mg/m^3 in the rat. The threshold concentration for irritative effects in cats is reported as 800 mg/m^3. An oral LD_{50} of 2100 mg liquid isoprene per kilogram of body weight and an intraperitoneal LD_{50} of 1400 mg/kg in the male rat have been determined. A single dermal exposure of rats to a 1-mL dose of liquid isoprene per kilogram body weight did not cause adverse symptoms or mortality [164], [165].

Toxicity after Repeated Exposure. Fischer 344 rats and B6C3F1 mice were exposed by inhalation for two weeks to atmospheric isoprene concentrations of 0, 438, 875, 1750, 3500, and 7000 ppm. The rats did not show any exposure-related changes (survival, clinical symptoms, body weight, biochemistry, hematology, macro- and micropathology). Mice at the 7000 ppm level only showed lower body weight gain, but the mice in all groups suffered from anemia, testicular atrophy, olfactory epithelial degeneration, and epithelial hyperplastic changes in the stomach. As in the case of 1,3-butadiene, mice therefore seem to be more susceptible than rats [166].

Repeated dermal exposure (2 applications of 500 µL on each of 5 consecutive days) to the ear of the rabbit caused only limited, reversible irritation [165]. No data on long-term inhalation exposure are available.

Mutagenicity. Isoprene and its monoepoxides do not induce point mutations in the Ames test. The dioxide of isoprene (2-methyl-1,2,3,4-diepoxybutane) was found to be mutagenic in this test system [167–170]. Due to some similarities with 1,3-butadiene in the formation of mutagenic metabolites the possible carcinogenic effects of isoprene need further evaluation.

Inhalative exposure of B6C3F1 mice to isoprene levels from 438 to 7000 ppm in air for 6 h/d on 12 days resulted in elevated frequencies of sister chromatid exchange indicating cytogenetic effects [171].

Reproduction. No data on reproductive or teratogenic effects are available.

Table 9. Production facilities for isoprene

Country	Company	Location	Capacity as 100 wt % isoprene, t/a [a]	Product [b]	Process [c]

[a] Capacities in 1987.
[b] C = concentrate; P = pure isoprene.
[c] ACN = acetonitrile; DMF = dimethylformamide.

Metabolism. Rodent mitochondrial fractions transformed isoprene to its monoepoxides 3,4-epoxy-3-methyl-1-butene and 3,4-epoxy-2-methyl-1-butene, leading finally to the corresponding diols. Minor oxidation of the more stable metabolite (3,4-epoxy-2-methyl-1-butene) to a diepoxide has been described [172], [173]. Isoprene is metabolized significantly in the respiratory tract. Up to atmospheric isoprene concentrations of about 300 ppm, metabolism is directly proportional to the exposure concentration [174], [175]; a saturation effect occurs at levels above 300 – 500 ppm. Mice metabolize isoprene at a higher rate than rats [174].

Isoprene is synthesized endogenously. The synthesis rate in unexposed mice and rats has been calculated to be $0.4\,\mu mol\,h^{-1}\,kg^{-1}$ and $1.9\,\mu mol\,h^{-1}\,kg^{-1}$, respectively [174].

Effects in Humans. Isoprene is narcotic in humans at very high exposure levels. It may also cause irritation of the skin, eye, mucous membranes, and respiratory tract.

Hygienic Standards. No TLV or MAK values have been established for isoprene. A threshold of 40 mg/m^3 has been set in the former Soviet Union.

∗ Year-end data, 1989 being based on available projections.

Table 11. Production and production capacity (in 10^3 t) for polyisoprene (IR), butyl rubber (IIR), and total synthetic rubber [163] ∗

		1979	1980	1981	1982	1983	1984	1985	1986	1987	1988	1989
IR	capacity	281	289	289	297	397	289	285	255	225	220	213
IR	production	242	219	168	129	120	146	110	132	113		
IIR	capacity	493	498	446	533	539	583	580	583	585	607	615
IIR	production	457	395	426	370	372						
Synthetic rubber	capacity	7975	8144	8379	8878	8944	8710	8639	8772	8730	8844	9108
Synthetic rubber	production	5830	6167	5347	5281	4623	4854	5397	5211	5486		

∗ Excluding countries with centrally planned economies.

1. Fundamentals

1.1. Definitions and Nomenclature

The term *nuclide* is used to indicate a species of atom characterized by the constituents of its nucleus; i.e., the number of protons Z (the atomic number) and the number of neutrons N. The total number of protons and neutrons, referred to nonspecifically as *nucleons,* is the mass number $A = Z + N$. The term *isotope* is used to define any of two or more nuclides that have the same atomic number Z but different atomic mass numbers A. Thus, isotopes of an element differ in the number of neutrons each contains. The definitions indicate that all isotopes are nuclides but all nuclides are not necessarily isotopes. Correct usage dictates that an element having only one naturally occurring species (e.g., fluorine) should be referred to as mononuclidic; monoisotopic is a contradictory term and should not be used.

The nomenclature used to identify nuclides employs the atomic mass number of the species as a superscript on the left of the chemical symbol of the element (e.g., ^{20}Ne, ^{196}Hg, and ^{202}Hg). In some publications, the mass number is written as a superscript to the right of the sym-

10.1002/14356007.a15_001

bol, but this position is properly reserved for the charge on an ionic species or for the indication of an excited state. The atomic number can be written as a subscript on the left of the symbol (e.g., $^{20}_{10}$Ne, $^{196}_{82}$Hg and $^{202}_{82}$Hg). The isotopes of hydrogen are probably the best known and most widely used nuclides, and have therefore been given individual names: ^{2}H is called *deuterium* and is abbreviated D; ^{3}H is called *tritium* and is abbreviated T. For consistency, the suggestion has been made that ^{1}H be called *protium* and that the term hydrogen should be used only to refer to the mixture of isotopes, but this has not been generally accepted. The term hydrogen is used in this chapter to refer to both the element and its most abundant isotope.

The presence of a variable number of neutrons in the nucleus of isotopes can affect the chemical reactivity of compounds, especially those containing isotopes of the lightest element, hydrogen. In general, however, isotopic effects are small compared to reactivity difference between elements. More prominent differences are noted in physical and nuclear properties among isotopes of the same element, where mass and magnetic properties play an important role.

1.2. Survey of Natural Nuclides

Natural nuclides are those present in the Earth's crust and atmosphere. At least one nuclide has been discovered on Earth for each element with atomic numbers 1 to 92, with the exception of technetium ($_{43}$Tc) and promethium ($_{61}$Pm). Isotopes of both these elements, however, have been identified in the spectral signature of some stars and have been produced artificially in the laboratory [1]. A minute quantity of an isotope of plutonium $^{244}_{94}$Pu has also been found in ores excavated in California [2]. The 91 naturally occurring elements consist of 327 nuclides. The existence of isotopes is common over much of the periodic table. Only 19 of the elements found on Earth are mononuclidic. Two other elements, bismuth and thorium, have only one naturally occurring stable isotope, but also have other isotopes that are members of radioactive decay series. Conversely, tin has ten isotopes, and 16 other elements have seven or more isotopes. Table 1 lists naturally occurring nuclides by atomic number and atomic mass number. Experimentally determined atomic masses and the abundance of each nuclide as a percentage for each element are also included.

The naturally occurring nuclides can be divided into two categories, stable and radioactive. This classification is, however, arbitrary in some cases. The group of 287 stable nuclides also includes isotopes of at least 17 elements that undergo radioactive decay but whose half-lifes are long with respect to geologic time (generally nuclides with half-lifes of ca. 10^9 a and longer are considered stable). A qualifier is used here because the radioactive decay of some nuclides, predicted theoretically, is confirmed experimentally from time to time. These species usually have extremely long half-lifes, which makes detection of nuclear reactions difficult (e.g., ^{82}Se, $t_{1/2}$ ca. 10^{20} a; see Section 3.1). At present, 14 nuclides of this type have been identified. The term stable might prove to be a misnomer because certain theories of nuclear physics suggest that the proton may be unstable to decay, with a half-life of $10^{30} - 10^{32}$ a [3]. Experimental results have not yet shown this to be true, but with events expected approximately once every hundred years, some time may be required for this conjecture to be proved or disproved.

The group of radioactive nuclides includes all the naturally occurring species with atomic number higher than 83 (bismuth), with the exception of one isotope of thorium (^{232}Th) and two isotopes of uranium (^{235}U and ^{238}U), whose halflives qualify them as stable. Of these 40 high-mass radioactive species, 39 are daughter nuclides in the decay series of thorium and uranium. The plutonium isotope ^{244}Pu goes through several decay steps and is eventually transformed into ^{232}Th. Although 20 nuclides with lower atomic numbers also undergo radioactive decay, 18 of these are regarded as stable. The two exceptions ^{3}H and ^{14}C have been identified in trace amounts in the Earth's atmosphere [4]. These radioactive species have relatively short half-lifes (12.26 and 5730 a, respectively) and are thought to be generated continually in small quantities by solar-related phenomena in the upper atmosphere. Table 2 gives information about naturally occurring radioactive isotopes, including half-life, decay mode, decay energy, and the product of nuclear reactions for each species.

Table 1. Naturally occurring nuclides

∗ EC = electron capture

Figure 1 shows a graph of the natural nuclides with the number of neutrons plotted against the number of protons; included in this figure are lines of constant mass. Note that the nuclides are generally grouped along the $N = Z$ line at low atomic numbers and have $N > Z$ as the atomic number increases. The stability of nuclides is a function of several factors, including the number of protons and the number of neutrons, the binding energy holding the nucleus together, and the availability of pathways for transforming one nucleus into another. Certain numbers of protons or neutrons appear to be particularly stable. In the case of protons, $_{20}$Ca and $_{50}$Sn have more isotopes (six and ten, respectively) than other elements in the vicinity of each of these species. The *nuclear shell theory* [5] explains this by invoking subshells that are filled sequentially as atomic number and atomic mass number increase, much as electron shells are filled. Protons and neutrons have separate subshells, but both have the same numerical configuration. Completely filled subshells are said to contain *magic numbers* of nucleons (2, 8, 20, 28, 50, 82, and 126) and confer added stability on the nucleus,

just as completely filled electron shells result in low chemical reactivity for the noble gases. The binding energy of a nucleus can be envisioned as a part of the mass that is converted to energy when a nucleus is formed from its constituent nucleons. The relative stability of a nuclide is found by calculating the binding energy per nucleon and comparing it with that of its neighboring species. For spontaneous decay to transform one nuclide into another, the product must be more stable than its precursor. Thus, $^{82}_{34}$Se does not decay to $^{82}_{35}$Br (by electron emission), $^{82}_{33}$As (by electron capture or positron emission), or $^{78}_{32}$Ge (by alpha emission), instead, it undergoes the rare double-beta decay to form $^{82}_{36}$Kr.

Several general features may be gleaned from Table 1 and Figure 1:

1) All but one ($^{9}_{4}$Be) of the mononuclidic elements have odd atomic numbers. Other odd-numbered elements have only two naturally occurring stable isotopes. Table 1 lists three isotopes for hydrogen and potassium, but ^{3}H and ^{40}K are radioactive and present in very small amounts.
2) Elements with $Z < 22$ are mononuclidic or have one predominant isotope; six are mononuclidic; five are at least 99 % abundant (^{12}C is 98.9 % abundant); six are at least 90 % abundant; three are at least 75 % abundant.
3) For elements with odd atomic numbers and $Z < 22$, the only nuclide, or the predominant isotope, has $N = Z + 1$, with hydrogen and nitrogen being exceptions.
4) For elements with even atomic numbers and $Z < 22$, the most abundant isotope has $N = Z$ (e.g., nitrogen). Argon is an exception.
5) At higher atomic numbers ($Z > 21$), the likelihood of a larger number of isotopes and a broader distribution of relative abundances increases. All of the elements with even atomic numbers have at least four isotopes. The occurrence of seven or more isotopes is common above niobium ($Z > 41$). Elements with odd atomic numbers that are not mononuclidic tend to have a more balanced distribution of isotopic abundances: copper, thallium, and rubidium, ca. 70 : 30; gallium, antimony, rhenium, and iridium, ca. 60 : 40; bromine, silver, and europium, ca. 50 : 50. Vanadium, lanthanum, lutetium, and tantalum do not fit this pattern. They each have one isotope that is at least 99 % abundant (97 % for Lu), but the less abundant species in these cases is radioactive. Indium is unusual in that its most abundant isotope (^{115}In, 95.7 %) is radioactive.
6) Figure 1 shows that as atomic number increases, the stable nuclides are those that are neutron rich (i.e., $N > Z$). In fact, no naturally occurring nuclides heavier than ^{3}He exist in which the number of protons is greater than the number of neutrons. The ratio of neutrons to protons is close to 1 : 1 at low atomic numbers but gradually increases to ca. 1.5 : 1 for the heaviest natural nuclides. One theory of nuclear structure suggests that as the number of positively charged protons increases, more neutrons are needed to separate positive charges.

Figure 1. Chart of natural nuclides
● Stable nuclides; ○ Radioactive nuclides with half-life $>10^8$ a

Table 1 lists the abundance of the nuclides found on Earth. By way of contrast, Figures 2 and 3 depict the relative abundances of elements and nuclides in the Solar System, expressed as number of atoms per 10^6 atoms of silicon [6].

The data are obtained from investigations of meteorites and the solar atmosphere. Values reflect the relative amounts of nuclides in the nebula from which the Solar System evolved, some 4×10^9 years ago. In some cases, these values do not correspond to the abundances found on Earth, especially for volatile elements and compounds. A striking example of this is argon, whose most abundant isotope on Earth is ^{40}Ar. The most abundant isotope (>99 %) in the Solar System is ^{36}Ar. The isotope ^{40}Ar found on Earth is almost exclusively a result of the decay of ^{40}K since the Earth was formed; the original argon, rich in ^{36}Ar, was lost through outgassing from the newly condensed matter that eventually became the Earth.

Figure 2. Abundance versus atomic number
∗ Number of atoms per 10^6 atoms of silicon

Figure 3. Abundance versus atomic mass number
∗ Number of atoms per 10^6 atoms of silicon

Figures 2 and 3, which plot relative abundance versus atomic number and atomic mass number, respectively, also show some general trends:

1) As atomic number increases, a near exponential decrease in abundance occurs from hydrogen through most of the second transition series (until ca. $Z = 42$ and $A = 100$). After that point, the decrease is more gradual and contains some peaks of relatively high abundance. Deuterium, beryllium, lithium, and boron do not follow the trend and are rare compared to other nuclides of similar mass.
2) Elements with even atomic numbers are more abundant than those with odd numbers in any given area of Figure 2 (except for Be).
3) Up to atomic number 40 (Ca), nuclides with a mass number that is a multiple of 4 are more abundant than their neighbors: $^{12}_{6}$C, $^{16}_{8}$O, $^{20}_{10}$Ne, $^{24}_{12}$Mg, $^{28}_{14}$Si, $^{32}_{16}$S, $^{36}_{18}$Ar, and $^{40}_{20}$Ca (again, except for Be).
4) Positions of even atomic mass number may be occupied by more than one nuclide. This is common above $A = 36$ and includes some mass numbers that correspond to three stable species, (e.g., $A = 96$). No stable species heavier than $^{14}_{7}$N has both an odd number of protons and an odd number of neutrons.
5) Positions of odd atomic mass numbers (even Z, odd N, and vice versa) are occupied by only one stable nuclide with the exception of $A = 113$ (isotopes of In and Cd). Other odd atomic mass number positions occupied by two species (87, 115, 123, and 187) include one radioactive nuclide. The odd atomic number species of each pair decays into an even atomic number species by electron emission (except $^{123}_{52}$Te, which decays by positron emission to $^{123}_{51}$Sb).
6) A large abundance peak occurs in the first transition series, centered at ^{56}Fe, where the abundance is about three orders of magnitude greater than that expected from the general trend. Other areas of locally higher abundance appear in Figure 3 at higher mass number.

1.3. Origins of Nuclides

Explanations for the trends in abundance of nuclides are found in the mechanisms of their creation. The origin of matter begins with the origin of the universe. One widely held theory of cosmological evolution is the big bang, proposed by ALPHER, BETHE, and GAMOW in 1948 [7], which postulates that matter was created from a suddenly expanding singularity. Later revisions of the original theory postulate that the initial form of matter was a mixture of leptons, including electrons, and quarks. The latter combined to form protons and neutrons. A neutron that is not confined in a nucleus decays into a proton, an electron, and an antineutrino with a half-life of ca. 11 min. Thus, the building blocks of the elements were created in the first hours of the universe. Conditions appear to have been appropriate for some helium to form in the initial cosmological fireball, but the majority of matter was in the form of hydrogen. This theory accounts for more than 99.9 % of the atoms that currently exist in the universe.

Nucleogenesis is the science that attempts to explain the origin of all nuclides found in the universe. For this purpose, processes that occur in the interior of stars must be examined. A comprehensive theory of nucleogenesis was presented by BURBIDGE, BURBIDGE, FOWLER, and HOYLE in 1957 [8]. This work is the basis for later discussions of elemental origin and abundance [9]. The theory postulates variations in the density of hydrogen in the primitive universe that allowed gravitational attraction to cause accretion of hydrogen and helium. As matter contracts under the force of gravity, the temperature rises until nuclear reactions begin in the core of what now can be called a star. The life cycle of a star involves a series of different types of nuclear processes, some of which are determined by the initial mass of materials that condense to form the star. As a star evolves, various processes become important as density and temperature change, and reactions that have already occurred provide material for subsequent reactions. The processes may be examined in three groups: (1) exothermic reactions, (2) neutron capture processes, and (3) miscellaneous processes both inside and outside of stars [10].

The initial reaction that occurs as the temperature of the contracting mass of material increases is hydrogen burning, an exothermic reaction. When the core of the star reaches ca. 10^7 K, the fusion of four hydrogen nuclei to form a helium nucleus becomes possible. Other nuclei, especially carbon and nitrogen, may catalyze the reaction. During this period, thermal pressure of radiation from the reaction halts further collapse of the star.

After a certain amount of helium has been produced, the thermal pressure is insufficient to offset gravitational attraction and contraction of the core is again possible, which increases the density and causes further heating. Above ca. 2×10^8 K, three helium nuclei may combine to form a carbon nucleus. This exothermic reaction involves the creation of a very short-lived intermediate ^{8}Be from two helium nuclei, which may then react with another helium nucleus to produce ^{12}C. Subsequent additions of helium nuclei result in the synthesis of oxygen, neon, and magnesium. As before, the stellar core eventually reaches the point of further gravitational collapse.

At ca. 5×10^8 K, carbon burning becomes possible. Two carbon nuclei may combine to form a magnesium nucleus, or to give lighter nuclei, hydrogen, and helium. Hydrogen and helium can participate in subsequent reactions to generate other nuclei in this mass range. Nuclear reactions similar to carbon burning may proceed in some stars that use other nuclei as fuels. After carbon is depleted, oxygen burning and then silicon burning are possible under appropriate conditions.

The next stage in stellar evolution depends on the mass of the star. If the stellar mass is less than about 1.5 solar masses (one solar mass is ca. 2×10^{30} kg), continued contraction of the core may occur, accompanied by increased heating. Above ca. 10^9 K, an exothermic process can occur that generates ^{16}O and ^{4}He from ^{20}Ne. This is the source of helium nuclei for the *alpha process,* which is responsible for the creation of nuclides having atomic mass numbers that are multiples of 4. This process stops at ^{40}Ca because the next member of the series, ^{44}Ti$*$ (the asterisk denotes an excited state), is unstable to decay by electron capture.

If the star is very massive (1.5 – 3.5 solar masses), its sequence is different from that described above. Hydrogen is consumed much more quickly, and helium reactions begin much

earlier. These conditions lead to instability, and the star disintegrates in a supernova explosion. Before this cataclysmic event, however, the temperature of the core rises above 3×10^9 K and many different nuclear reactions involving neutrons, protons, and gamma rays occur in great numbers. In a short time, a statistical equilibrium is established among the various nuclei and nuclear particles. Especially prominent as a result of this series of exothermic reactions, termed the *e-process,* are the nuclei of the elements with atomic numbers 22 – 29 (the first-row transition metals). Their abundances are determined by the magnitude of the binding energy associated with the various nuclei. The most stable nucleus with the highest binding energy per nucleon is ^{56}Fe, which is also the most abundant nuclide in this mass range (see Fig. 2).

Other nuclear reactions are associated with conditions immediately preceding a supernova explosion and are believed to be responsible for the production of some isotopes of the heavier elements. Proton capture may explain formation of the lighter isotopes of some heavier elements (e.g., ^{74}Se, ^{120}Te, and ^{196}Hg). These isotopes, which have a higher ratio of protons to neutrons than other isotopes, are usually present in only small amounts compared to the abundance of isotopes produced by means other than proton capture.

Neutron absorption processes are thought to be responsible for creation of the majority of heavy nuclides. Rapid neutron capture, the *r-process,* may also occur in unstable massive stars about to disintegrate in a supernova explosion. In a matter of seconds a large number of neutrons may be added to a nucleus. Absorption continues until the neutron capture cross section of the resulting nucleus diminishes to the point at which the unstable species has time to decay (after absorbing as many as 100 neutrons). Numerous beta emissions give rise to neutron-rich heavier isotopes such as ^{82}Se, ^{134}Xe, and ^{198}Pt. The lower mass parts of the double-peaked abundance maxima (see Fig. 3) near $A = 80$, 130, and 194 are the results of unstable nuclei with neutron quantities near the magic numbers undergoing these types of reaction. In addition, some of the lighter isotopes (^{36}S and ^{48}Ca) that have no other obvious method of creation are thought to be products of the r-process.

The more common neutron absorption process is slow neutron capture, the *s-process.* These reactions occur in the outer atmosphere of less massive stars over much longer time periods, hundreds or thousands of years for the s-process as opposed to seconds for the r-process. Again, neutron capture cross sections play an important role in determining which nuclides have higher relative abundance. In this case, because beta emission may occur before further neutron absorption, the most abundant species formed are those with magic numbers of neutrons. Thus, the higher mass parts of the double-peaked maxima (e.g., $^{90}_{40}$Zr, $^{138}_{56}$Ba, and $^{208}_{82}$Pb) are a result of the s-process.

The existence of some nuclides cannot be explained by the various processes that occur within stars. These are the nuclides with atomic numbers lower than carbon and, as shown in Figure 2, abnormally low abundance; i.e., ^{2}H, ^{3}He, ^{6}Li, ^{7}Li, ^{9}Be, ^{10}B, and ^{11}B. Although ^{2}H and ^{3}He nuclei are intermediate products of hydrogen burning, they are almost completely consumed in this process. None of the other nuclei result from the processes described above. In addition, except for ^{3}He, none of these nuclei are stable above ca. 5×10^6 K, which is well below the temperature at which nuclear synthesis begins in the core of stars. Initially, the unknown method of synthesis of these nuclides was termed the *x-process.* It is now believed that several different reactions, all occurring exterior to stars, are responsible for their creation.

The majority of ^{2}H and ^{3}He is thought to have been formed, along with the vastly greater amount of ^{1}H, early in the universe. Boron isotopes and ^{7}Li are predominantly the products of proton capture reactions in interstellar space as a result of the high temperature generated by supernova shock waves. Other nuclides in this group appear to be almost exclusively the products of interstellar spallation reactions. Such reactions may result when cosmic rays, a variety of atomic particles traveling at relativistic speeds, collide with other atoms in the interstellar gas. If the incident particle is of low mass (^{1}H or ^{4}He), it can enter the nucleus of a higher mass target atom. Several nucleons may be ejected immediately from the target, leaving a nucleus in a highly excited state. The energy of this species is redistributed, and a number of nucleons are emitted (commonly, 10 – 20), individually or in

clusters. In this manner, ^{6}Li and ^{9}Be, and possibly some ^{2}H and ^{3}He, are created.

The above discussions concern naturally occurring stable nuclides. All nuclides with atomic numbers higher than 83 are radioactive. The occurrence of these nuclides in nature is explained by the decay series of their long-lived precursors, and their abundance is determined by the half-lifes of the various species from which they derive. The precursors of the three known radioactive series, ^{232}Th for the thorium series, ^{238}U for the uranium series, and ^{235}U for the actinium series, are created by rapid neutron capture processes during supernova explosions. The half-life of ^{232}Th (1.4×10^{10} a) is commensurate with the age of the universe. The isotopes of uranium were probably synthesized in many supernova explosions starting around 10^{10} years ago, before the formation of the Solar System or the Earth (ca. $4.5-5\times10^{9}$ years ago). Studies of the formation and decay of these nuclides also give an approximate age to the Milky Way galaxy just slightly less than the age of the universe (ca. $1.5-2\times10^{10}$ years).

Thus, through a variety of processes, the synthesis of naturally occurring nuclides can be explained and their relative abundances accounted for. Some of the theoretical computations of these processes can be made quite accurately, especially in situations where statistical equilibrium applies. However, the great number of possible reactions and the inability to determine precise reaction rates or conditions, especially during supernova explosions, make computation difficult.

1.4. Discovery of Isotopes

The discovery of isotopes resulted from the study of radioactivity and radioactive elements. By the early 1900s, more than 30 different radioactive species were known. The chemical properties of these species, however, suggested that they should occupy no more than 12 positions in the periodic table. The chemical equivalence of groups of radioactive species such as ionium, thorium, and radiothorium (now known to be ^{230}Th, ^{232}Th, and ^{228}Th); radium and mesothorium-1 (^{226}Ra and ^{228}Ra); and ordinary lead (with an atomic mass of 207.2) and radium-D (^{208}Pb) was well established. Frederick Soddy generalized that all species occupying the same position in the periodic table are chemically identical and inseparable by chemical means and proposed that such species be called isotopes [11].

At that time, the atomic mass of an element was thought to be the major determinant of its chemical properties. Investigations showed that species with different atomic masses could have the same chemical properties. Conversely, other groups of radioelements were discovered that had essentially the same atomic mass but different properties (e.g., radium-B, radium-C, and radium-C' are now known to be ^{214}Pb, ^{214}Bi, and ^{214}Po, respectively). Such species are called *isobars* (→ Radionuclides).

In 1913, schemes were proposed for the various radioactive decay series in which emission of an alpha particle (a helium nucleus) moves a radionuclide two places in the periodic chart to a lower group, with an atomic mass number four units less, and emission of a beta particle (an electron) results in a change to the next highest group, with no change in the mass number. Emissions from radioactive species were also known to be charged particles, the alpha particle carrying two positive charges and the beta particle a single negative charge. The combination of these findings led to the idea that a relationship existed between the charge of the nucleus and its position in the periodic table, later to be quantified by the atomic number. The idea was first formally published in 1913 by A. van den Broek in connection with work on characteristic X-ray scattering of light elements. This determines the number of electrons in an atom, which is equal to the positive nuclear charge [11, p. 61]. A change to the next lowest group was later discovered to result from decay involving emission of a positron (the antiparticle of the electron) with the same mass and spin as the electron but a positive electrical charge. Evidence for the chemical equivalence of isotopes provided another fact in support of the theory.

Definite proof for the existence of isotopes was supplied by studies of the atomic mass of lead [12]. In 1913, radium-G, the final product in the uranium decay series, was found to be chemically identical to ordinary lead. The same conclusion was reached for the final products of the thorium and actinium series (thorium-D and actinium-D), but the differences in atomic

mass were recognized, even though the same element was being produced by radioactive decay. In 1914, SODDY and HYMAN showed that lead obtained from thorite, a mineral containing very little uranium, had an atomic mass almost one unit higher than ordinary lead. In the same year, LEMBERT and RICHARDS determined that the atomic mass of lead obtained from several uranium ores was almost one unit less than that of ordinary lead. These results were confirmed in independent studies and provided powerful support for the group displacement law and the theory of radioactive decay. More important, the results showed that a nonradioactive element could exist in several isotopic forms, all having identical chemical properties.

At the same time that the above studies were being conducted with high-mass elements, work in a seemingly unrelated field with lighter elements showed the phenomenon of isotopy to be universal. In 1912, J. J. THOMPSON was working in the area of *positive-ray analysis,* the study of charged particles produced by passing an electric arc through a gas at low pressure. A beam of positively charged molecules or atoms was known to be deflected from a straight line into a parabolic curve by an electric or magnetic field. The curve is determined by the charge-to-mass ratio *m/e* of the particles. In his analysis of the positive rays produced from a discharge tube containing neon, THOMPSON found not only the expected curve corresponding to an *m/e* of 20, but also a curve indicating a particle with an *m/e* of 22. The first explanation for this unexpected result was contamination by carbon dioxide (mass 44) with a double positive charge, but the curve still remained when the carbon dioxide was removed. THOMPSON concluded that neon must be a mixture of two gases with masses of 20 and 22. Attempts to separate the two gases were undertaken by F. W. ASTON [13]. Fractional distillation proved to be ineffective, but repeated diffusion through clay tubes gave two fractions whose atomic masses were higher and lower than that of ordinary neon. Positive-ray analysis of these fractions showed curves at *m/e* values of 20 and 22, but with appreciable differences in intensity compared to ordinary neon. The emission spectra of both fractions, however, were identical to that of ordinary neon. The implication was that neon consists of two isotopes of masses 20 and 22.

In 1919, ASTON resumed his research on neon. He constructed an apparatus, the *mass spectrograph,* which focused the particles produced in a discharge tube into lines called a *mass spectrum* with much higher accuracy than had been previously achieved. The mass spectrum of neon confirmed the presence of two components with atomic masses 20 and 22. Moreover, the ratio of the lighter to the heavier component was found to be approximately 10 : 1, indicating a mean atomic mass of 20.2. This was in excellent agreement with the known atomic mass of neon.

In 1920, ASTON examined the mass spectra of nineteen elements and discovered that nine of these were composed of two or more isotopes. Each isotope was found to have a mass that was very close to an integer. For those elements that exhibited isotopy, the relative abundances and masses of the isotopes combined to give atomic masses close to the known values. The elements with atomic masses close to integers, such as helium, carbon, nitrogen, oxygen, and fluorine, were found to be mononuclidic. (Later work showed that some of these elements do have more than one isotope, but that one of these is present in 99 % or higher abundance.) These discoveries led ASTON to formulate the "whole-number rule," which states that all atomic masses are very close to integers and fractional elemental masses are a result of the presence of isotopes, each of which has an approximately integral mass and contributes to the elemental mass in proportion to its relative abundance.

The universality of the whole-number rule was confirmed by experiments performed by A. J. DEMPSTER at the same time. DEMPSTER's version of the mass spectrograph allowed determination of the relative proportions as well as the masses of isotopes. DEMPSTER showed that lithium, magnesium, potassium, calcium, and zinc are composed of isotopes of approximately integral atomic masses. Thus, by 1921, the existence of isotopes was widely accepted. The fact that each nuclide has an approximately integral mass allows the idea that each atomic nucleus contains a definite number of neutrons and protons which each have a mass that is close to unity on the atomic mass scale.

1.5. Determination of Isotopic Masses and Abundance

The mass spectrographs developed by ASTON and DEMPSTER were the first instruments to discern ions having different mass-to-charge ratios with any degree of accuracy. Improvements in design and electronics afforded greater accuracy in determining atomic mass and abundance. Initially, the equipment was used almost exclusively to study isotopes, but since the late 1940s many other applications have been found. Modern equipment (the *mass spectrometer*) is used to identify the components of complex organic mixtures, elucidate molecular structures and chemical reaction pathways, and analyze the composition of solid-state samples [14]. High-resolution mass spectrometers have the ability to separate ions whose masses differ by less than one part in 30 000, and other specialized equipment can analyze extremely small samples of gas (as little as 10^{-12} mol of material may be required for analysis).

DEMPSTER's spectrometer used a method known as *directional focusing,* in which ions are accelerated by an electric potential and then forced by a magnetic field to travel in a circular path to impinge on a detector. If the position of the detector is fixed and the magnetic field strength is constant, the magnitude of the electric potential may be varied, causing ions with a particular *m/e* ratio to be collected by the detector. The mass can be calculated if the charge on the ions is assumed to be constant. Absolute values of the various factors need not be known if the apparatus is calibrated with samples of known mass.

Another type of mass spectrometer employs velocity focusing. Ionized particles are subjected simultaneously to opposing magnetic and electric fields. Those ions unaffected by the combined fields (i.e., having a characteristic velocity) pass into the next portion of the analyzer, where they are subjected to another magnetic field, deflected into circular paths determined by the *m/e* ratio of each particle, and impinge on different parts of the detector.

Modern spectrometers employ both types of focusing (double focusing). A schematic of a double-focusing mass spectrometer is shown in Figure 4. These take advantage of the line sharpness available from directional focusing and the simple relationship between particle mass and position of detection of the velocity focusing technique.

Figure 4. Double-focusing mass spectrometer
a) Sample electrode (or inlet gas system) and ion source; b) Accelerating electrostatic slits; c) Electrostatic analyzer; d) Intermediate image slit and beam monitor electrodes; e) Magnetic analyzer; f) Focal plane; g) Auxiliary collector and electron multiplier; h) Amplification and recording

Other types of instrument dispense with the magnetic field. The *time-of-flight* mass spectrometer generates ions in very small pulses, all with the same kinetic energy. The masses are determined by measuring the time required for them to strike the detector. *Radio-frequency* (rf) mass spectrometers employ a charged grid with alternating steady and variable electric potentials to selectively accelerate ions with an *m/e* that are in phase with the varying potential. The mass of the ions is proportional to the frequency and the grid spacing. The *quadrupole* mass spectrometer also uses variable radio frequency to separate ions. Equal but opposite electrical potentials, with both d.c. and rf components, are applied to the two pairs of conducting rods that make up the analyzer portion of the instrument. Ions injected along the axis of the region formed by the poles are made to oscillate by alternating the rf portion of the electric potential. Those ions having a *m/e* ratio in resonance with the frequency of the alternating potential travel the length of the analyzer and into the detector portion of the apparatus.

Double-focusing mass spectrometers have been adapted to determine the percent abundance of isotopes. The *isotope ratio spectrometer* employs two detectors, and ion currents from two ion beams (e.g., $^{10}BF_3$ and $^{11}BF_3$) are mea-

sured simultaneously. Determining the ratio of the intensities of the ion currents then gives the isotopic ratio. This method eliminates virtually all variables that can arise from internal and external sources. It is also used in analysis of tracer materials for isotopic labeling, medical research, and radioisotopic dating studies.

The relatively great difference in physical properties between the isotopes of hydrogen allows physical measurements to be used in determining the isotopic abundance of hydrogen and hydrogen-containing compounds [15]. Methods include density by the flotation method, near- and middle-infrared absorption spectroscopy, and refractive index.

1.6. Atomic Mass Scales

Atomic masses have always been of great importance, and values have been updated and refined continually since the early 1800s [16]. In 1874, the American Chemical Society published a table of atomic masses for 64 elements; all values were integers. Presently, atomic masses are given to a precision of one part in 10^4 for most elements and one part in 10^6 for some. The atomic masses of all but ten elements (Ti, Zn, Ge, Se, Mo, Sn, Sb, Te, Hg, and Tl) are determined partially or entirely by mass spectroscopy. Masses of the remaining elements are still determined by chemical means, and all except antimony have a large number of isotopes: Ti, Zn and Ge have five; Se and Tl have six; Mo and Hg have seven; Te has eight; Sn has ten; and Sb has two.

Before 1962, the atomic mass scale used in mass spectroscopy employed ^{16}O (99.76 % abundance) as the standard. It was assigned a mass of exactly 16.0000. At the same time, atomic masses determined by chemical techniques were based on atmospheric oxygen having an atomic mass of 16.0000. Since ordinary oxygen has naturally occurring isotopes of mass numbers 16, 17, and 18, the chemical standard had a mass of 16.0045 on the spectroscopic scale. In 1962, the International Union of Pure and Applied Chemistry and the International Union of Pure and Applied Physics adopted a new scale based on a value of 12.0000 for the atomic mass of ^{12}C.

Atomic masses of the 19 elements with only one nuclide (see Table 1) can be determined most precisely. Those elements with one predominant isotope (H, He, N, O, Ar, La, Ta, and U) may also be measured very precisely. Atomic masses of elements with a large number of isotopes and a broad distribution of abundance are the most difficult to measure. Mass spectroscopic methods rely on determining both the mass and the abundance of all isotopes of an element and combining these values to give a weighted average. Most often, chemical methods are used in conjunction with mass spectroscopic methods for such elements.

1.7. Variations in Abundance

For many elements, the atomic mass cannot be more precisely determined because of variations in isotopic abundance of the naturally occurring materials. One reason for uncertainty is exemplified by lead. Because three of the isotopes of lead (^{206}Pb, ^{207}Pb, and ^{208}Pb) are final products of the three radioactive decay series, the atomic mass of any specific sample of lead depends on the particular mixture of radioactive precursors in the ore from which it comes. Although the atomic mass of a specific sample can be determined quite precisely, the tabulated atomic mass must take into consideration the variation of almost two mass units that may occur in samples of different origin. Thirty other elements either have isotopes that are radioactive or are the products of radioactive decay, and are subject to the same uncertainty.

A different situation involves hydrogen, an element with one overwhelmingly abundant isotope whose atomic mass cannot be given more precisely. The significant difference in masses of deuterium and protium results in differences in the physical properties of their compounds. The variation in properties may allow enrichment of one isotope to occur through natural processes. In addition, the method used to prepare the element may result in a change in the isotopic ratio and, therefore, the atomic mass of hydrogen. Electrolysis of water breaks down D_2O and HDO more slowly than H_2O, and therefore gives hydrogen with a lower atomic mass than that obtained by other methods.

The atomic mass of sulfur can vary by as much as 0.01 mass units from source to source. Samples of naturally occurring boron are known

to vary by as much as 0.07 % in atomic mass. Other elements in this category include lithium, carbon, oxygen, argon, and copper.

At present, tables of atomic mass are footnoted to indicate those elements that may deviate from published values because of radioactive decay, natural or artificial enrichment activities, and place of origin.

Variation in the natural abundance of isotopes is an important part of geochemistry [17]. Determination of the relative differences in abundance among particular samples goes hand in hand with the study of chemical reactions in geological and biological systems. Variations in isotopes in natural settings can be significant because of the large quantities of material and long periods of time involved. In addition to the study of isotope ratios on Earth, the study of meterorites allows determination of the abundance of nuclides in the early Solar System and provides evidence for their origin (see Section 1.3). Rocks gathered from the Moon show it to have extremely low amounts of carbon and nitrogen. Oxygen-containing minerals taken from its surface have a much narrower range of isotopic ratios than found on Earth. Interplanetary probes have gathered information about the isotopic ratios of the atmospheres of Venus and Mars. Both planets have carbon and oxygen isotopic ratios close to that of Earth, whereas Mars has a large enrichment of ^{15}N (ca. 75 % greater than Earth) and Venus has an enormous (100-fold) relative enrichment of deuterium. Such studies aid in determination of the geological history of the Solar System.

2. Properties of Isotopes

Variation in the number of neutrons in the nucleus can result in different properties for isotopes of an element; these differences are known as *isotope effects.* Physical effects are noticed in the two general areas of mass effects and nuclear effects. Chemical differences are manifest in reactivity effects, including equilibrium and rate-determining (kinetic) effects as well as chemical bonding and structural effects. Physical differences among isotopes are generally the most pronounced, whereas chemical differences are more subtle. The effects of isotopy are particularly great for the lightest elements, which have larger relative mass differences between isotopes than the heavier elements. Although the differences that result from isotope effects are usually very small, they can be identified readily with the sophisticated techniques and sensitive instrumentation currently available and are useful in some applications.

2.1. Physical Differences

2.1.1. Mass Effects

Table 3. Physical properties of H_2, HD, and D_2

Property	H_2	HD	D_2
M_r	2.01588	3.0238	4.0318
mp, K	14.01		18.55
Heat of fusion, J/mol	117.1	159.4	196.6
bp, K	20.39	22.13	23.67
Heat of vaporization, J/mol	903	1074	1225
Density (liquid), g/cm^3	0.070		0.169
Triple point			
Temperature, K	13.96	16.0	18.73
Pressure, Pa	7300	12 800	17 700
Critical point			
Temperature, K	33.24	35.91	38.35
Pressure, kPa	1341	1534	1720
Volume, mL/mol	65.5	62.3	60.3
Dissociation energy, kJ/mol	431.6	435.1	439.2
Zero-point energy, kJ/mol	25.96	22.53	18.44

Because the existence of isotopes results from a difference in the number of neutrons in the nucleus, differences in mass-related phenomena among isotopically different elements and molecules are to be expected. Such phenomena include density, viscosity, thermal conductivity, diffusivity, and surface tension. The vibrational energy of a chemical bond depends on the masses of the atoms that make up the bond because the frequency of vibration is inversely proportional to the square of the mass. Isotopic differences change the bond vibrational energies and, therefore, the zero-point energies; this leads to variations in bond dissociation energy and enthalpies of fusion and vaporization. These variations result in changes in the melting and boiling points of isotopically different elements and compounds. For example, molecular deuterium (D_2) boils 3.12 °C higher than H_2, and heavy water (D_2O) boils 1.43 °C higher than H_2O. Table 3 presents the physical properties of H_2, D_2, and HD. Table 4 compares H_2O

and D_2O, which show large isotope effects because of the difference of a factor of two in the masses of hydrogen and deuterium and lesser effects because of the differences between ^{16}O and ^{18}O.

Table 4. Physical properties of H_2O and D_2O

Property	H_2O	D_2O

Absorption spectra of molecules exhibit isotope effects because they result from transitions between vibrational and rotational energy levels in molecules (coupled with a nuclear spin component). Vibrational energy levels depend on the masses of the nuclides involved in a bond, while rotational energy levels are related to the center of mass of a molecule. Both quantities change with isotope substitution. Figure 5 shows part of the infrared spectrum of hydrogen chloride, with 12 pairs of rotational bands superimposed on a single vibrational band. In each pair of rotational bands, the transition at higher energy is related to ^{37}Cl and at lower energy to ^{35}Cl. Measurements of the *isotopic line shift* can be made very accurately in the microwave region of the spectrum and are a basis for determining isotopic ratio and abundance [18].

Electronic energy levels are also affected by isotopic differences. Optical emission spectra are dependent on the reduced mass of the species involved. The wave number, ν (the reciprocal wavelength) of the light emitted is given by

$$\bar{\nu}=R_\infty Z^2 \frac{\mu}{m_e}\left[\frac{1}{n_1^2}-\frac{1}{n_2^2}\right] \quad (1)$$

where R is the Rydberg constant, Z is the atomic number, m_e is the mass of the electron, n_1 and n_2 are the main quantum numbers of the lower and higher electron orbitals of the transition, and μ is the reduced mass, given by

$$1/\mu = 1/m_e + 1/m_n \quad (2)$$

where m_n is the mass of the nucleus. Thus, the wave number of the emission increases with increasing mass of the nucleus, i.e., emission occurs at higher energy. The isotopes of hydrogen give the largest line shifts; the H_a emission line is 0.179 nm higher for D_2 than H_2. This difference was predicted theoretically and confirmed experimentally by Urey in 1932, providing the first evidence for the existence of deuterium [19]. Differences in reduced mass become less significant with heavier elements. However, changes in nuclear size and shape also affect transition energies, and significant effects from these changes can be found between isotopes of heavier elements. For ^{235}U and ^{238}U, the isotopic shift is 0.025 nm (ca. 14 % of the hydrogen-deuterium shift) even though the reduced mass difference of these uranium isotopes is only ca. 1 % that of the hydrogen isotopes. An element with many isotopes may exhibit more complicated isotope effects in its spectrum. Figure 6 shows the hyperfine splitting of one of the resonance lines in the emission spectrum of mercury, with ten peaks at 40 °C and five at 15 °C. These multiple emission lines are attributed to the seven isotopes that make up the element, with certain isotopes having more than one emission in the region shown. Overlap of peaks occurs at lower temperature.

Mass-related effects are also found in the behavior of high-temperature oxide superconductors [20]; e.g., $La_{1.85}Sr_{0.15}CuO_4$, which has a transition temperature T_c to the superconducting state of ca. 37 K, and $YBa_2Cu_3O_7$, which has a T_c of ca. 92 K. According to theory, the T_c of a material depends on the frequency of lattice vibrations. Thus, an isotope effect is expected

Figure 5. Portion of the infrared absorption spectrum of HCl

because the vibrational frequency is related to the mass of the nuclei that form the lattice. Evidence [21] has confirmed that high-temperature oxide species exhibit an isotope effect when ^{18}O is substituted for ^{16}O, the T_c is lowered by ca. 1 K in both cases (this may be reversed by resubstitution of ^{16}O). However, the shift in T_c calculated theoretically is much higher than the experimentally determined value; it is twice as great when calculated for the lanthanum compound and five times greater for the yttrium species.

Figure 6. Portion of the emission spectrum of mercury

2.1.2. Nuclear Effects

In addition to its mass, other properties of the nucleus are affected by the number of neutrons. The stability of the nucleus depends on the nucleon composition. Nuclear theory suggests that protons pair with protons and neutrons with neutrons. The most stable nuclei are those with even numbers of both nucleons. Unpaired protons or neutrons lead to lower stability and may result in radioactive decay, which produces a more stable nuclear configuration. An example is ^{40}K, a radioactive species with 19 protons and 21 neutrons. This isotope decays by negative beta (β^-) emission to form ^{40}Ca, with 20 protons and 20 neutrons; the unpaired neutron is converted to a proton, an electron, and a neutrino. The species also decays by either positive beta (β^+, positron) emission or orbital electron capture to form ^{40}Ar, with 18 protons and 22 neutrons; the unpaired proton is converted to a neutron, a positron, and a neutrino in the first case, and to a neutron and a neutrino in the second case. Pairing of nucleons also determines nuclear spin I. Nonzero nuclear spin results in a magnetic moment for a nucleus which may interact with electric and magnetic fields. This property is exploited in chemical analysis by nuclear magnetic resonance (see Section 3.1).

The total number of nucleons has another effect on the absorption spectra of some molecules in addition to the isotope shift caused by mass differences. Nuclei with an odd atomic mass number are governed by Fermi – Dirac quantum statistics and are referred to as *fermions,* whereas nuclei with an even atomic mass number obey Bose – Einstein quantum statistics and are known as *bosons* [22]. The different quantum statistical treatments determine which specific rotational transitions of a diatomic molecule are allowed and which are forbidden. Thus, the infrared spectra of $^{16}O_2$ and $^{17}O_2$ show different

relative intensities for the rotational transition lines. The nuclear spin can affect other properties, as exemplified by the fact that the boson ^{4}He becomes a superfluid at low temperature, whereas the fermion ^{3}He does not exhibit superfluidity. In the hydrogen molecule, each of the two nuclei (protons) has a spin of 1/2. The spins may be paired or unpaired, resulting in molecules of different energies with measurable property differences. When the spins are paired ($I = 0$), the species is known as *para hydrogen.* When the spins are unpaired ($I = 1$), the molecule is known as *ortho hydrogen.* Under normal conditions, the ratio of ortho to para is 3 : 1. Although not strictly an isotope effect, the ortho and para molecules do show differences in physical properties.

2.2. Chemical Differences

2.2.1. Equilibrium Effects

In a chemical reaction involving molecules with a common element (e.g., AX and BX), the common element X may be exchanged between the molecules. If the common element consists of isotopes (X and X∗), these may be involved in the exchange reaction:

$$\mathrm{AX} + \mathrm{BX}* \rightleftharpoons \mathrm{AX}* + \mathrm{BX} \tag{3}$$

The equilibrium constant K for the reaction is approximated by the equation

$$K = \frac{[\mathrm{AX}^*]\,[\mathrm{BX}]}{[\mathrm{AX}]\,[\mathrm{BX}^*]} \tag{4}$$

If the equilibrium constant for this reaction deviates from unity, a noticeable isotope effect occurs. A value higher than 1 favors the forward reaction, and the isotope X∗ is preferentially associated with the AX∗ species; a value lower than 1 favors the reverse reaction and results in enrichment of the X∗ isotope in the form of the BX∗ molecule.

Statistical thermodynamics provides the explanation for this phenomenon and allows calculation of the magnitude of the effect [4, app. B]. The equilibrium constant may also be written in terms of partition functions:

$$K = \frac{Q_{\mathrm{AX}^*} Q_{\mathrm{BX}}}{Q_{\mathrm{AX}} Q_{\mathrm{BX}^*}} \tag{5}$$

where Q is the grand partition function for each molecule and includes all possible energy states of that molecule. These energy states may be represented by the individual partition functions for the various forms of energy: translation (Q_{tr}), rotation (Q_{rot}), vibration (Q_{vib}), electron movement (Q_{el}), and nuclear spin (Q_{nsp}). The grand partition function is, therefore,

$$Q = Q_{\mathrm{tr}} Q_{\mathrm{rot}} Q_{\mathrm{vib}} Q_{\mathrm{el}} Q_{\mathrm{nsp}} \tag{6}$$

All these partition functions are important in explaining the physical differences among isotopes, but only the first three influence the chemical equilibrium isotope effect. The equation describing the translational energy of a molecule includes terms for the mass and the molar volume of the molecule, both of which are affected by isotopic differences. Equations for the rotational and vibrational energies both include a term for the reduced mass of the molecule. Thus, the mass of the molecule enters into the partition functions for all three modes of molecular motion. The largest isotope effect is found in the vibrational energy levels, which are important in the transition states of chemical reactions. Temperature is also a factor in the translational energy partition function, which indicates that isotopic exchange reactions are temperature dependent. Thus, the mass difference between isotopes may alter the exchange reaction to favor the association of one isotope with a particular compound in a given chemical reaction.

An example of the isotope effect is the exchange reaction of oxygen isotopes between carbonate ions and water:

$$\mathrm{C}^{16}\mathrm{O}_3^{2-} + \mathrm{H}_2^{18}\mathrm{O} \rightleftharpoons \mathrm{C}^{18}\mathrm{O}^{16}\mathrm{O}_2^{2-} + \mathrm{H}_2^{16}\mathrm{O} \tag{7}$$

The equilibrium constant K for this reaction is 1.112 at 0 °C. The isotope effect is, therefore, 11.2 % in this case and results in the enrichment of ^{18}O in the carbonate that precipitates from solution. Since the equilibrium constant is temperature dependent, the ratio of ^{18}O to ^{16}O is also a function of temperature. Thus, the analysis of precipitated carbonates can be used to obtain information on geological temperature. Isotope effects are common in biological systems and may be quite significant for the lighter elements, especially hydrogen. Certain algae and bacteria

prefer deuterium to hydrogen and show enrichment factors up to 4. Other microorganisms survive in environments where the isotopic abundance differs markedly from natural abundance; this is not the case for higher organisms. Some reactions, such as the exchange of hydrogen isotopes between water and hydrogen sulfide (see Section 4.2.6), exhibit sufficiently large isotope effects for them to be used in industrial processes to enrich isotopes. Note that even when these examples are cited as systems in which the effects are quite large, they are still small by normal chemical reaction criteria; for most elements, isotope effects are small enough to be neglected in everyday experimental or commercial systems. Fortunately, this means that isotopic tracers can be used in chemical systems without undue complications.

2.2.2. Kinetic Effects

In a simple chemical reaction, the rate of reaction is proportional to the concentration of reactants. For isotopically substituted species [23], these reactions might be

$$\begin{aligned} &\mathrm{A+BC \longrightarrow AB+C} \\ &\mathrm{A+B{*}C \longrightarrow AB{*}+C} \end{aligned} \tag{8}$$

and the expressions for the reactions rates are

$$\begin{aligned} \frac{\mathrm{d\,[A]}}{\mathrm{d}t} &= K\,[\mathrm{A}]\,[\mathrm{BC}] \\ \frac{\mathrm{d\,[A]}}{\mathrm{d}t} &= K'\,[\mathrm{A}]\,[\mathrm{B^*C}] \end{aligned} \tag{9}$$

where K and K' are rate constants for the reactions. Each reaction is assumed to take place by way of a transition state known as the activated complex:

$$\begin{aligned} &\mathrm{A+BC \rightleftharpoons ABC^{\#} \longrightarrow AB+C} \\ &\mathrm{A+B{*}C \rightleftharpoons AB{*}C^{\#} \rightleftharpoons AB{*}+C} \end{aligned} \tag{10}$$

where # indicates a short-lived transition state. The activated complex is a combination of the reacting species, and possesses its own bonding scheme and vibrational frequencies. The transition state lies at an energy above that of the reactants; the difference is the activation energy. Once formed, the complex may decompose either into the products or back to the reactants. Activated complex theory states that an equilibrium is established between the reactants and the activated complex and that the rate constant for the overall reactions is proportional to the equilibrium constants for the formation of the activated complex. The rate constants for the isotopically substituted species are

$$\begin{aligned} k &= (k_{\mathrm{B}}\,T/h)\,K^{\#} \\ k' &= (k_{\mathrm{B}}\,T/h)\,K'^{\#} \end{aligned} \tag{11}$$

where k_{B} is the Boltzmann constant, $K^{\#}$ and $K'^{\#}$ are equilibrium constants for the formation of the transition states, h is Planck's constant, and $k_{\mathrm{B}}\,T/h$ is essentially the average lifetime of the activated complex. The equilibrium constant for the activated complex may be represented as a ratio of grand partition functions for the reactants and, in these cases, the activated complexes. The form of the partition function for the activated complex is slightly different from those of the reactants because of restrictions in its degrees of freedom. The motion, and thus the available energy states, of the activated complex are limited to the reaction coordinate, i.e., by the nature of the reacting species and how they combine in the transition state. Nevertheless, three of the four terms involved in the grand partition function depend on vibrational frequencies, which are mass dependent. For a kinetic isotope effect to exist, the vibrational frequencies of the activated complex must differ from those of the reactants and must involve motion of the isotopically different atoms B or B∗. If these conditions are not met, only an equilibrium isotope effect is seen.

Kinetic isotope effects usually result in a reduction in reaction rate when heavier nuclides are substituted for lighter ones. Kinetic effects tend to be larger than equilibrium effects because the difference in activation energies of the reactions is usually greater than the difference in the enthalpies of the reactions for isotopically substituted molecules.

The kinetic isotope effect has proved useful in elucidating reaction mechanisms and identifying the rate-determining step for some organic reactions. The mechanism for electrophilic aromatic substitution was shown to be a two-step reaction involving an intermediate. Other uses could take into consideration the slower reactions that result from substitution of heavier isotopes for lighter ones. Deuteration (replacing

hydrogen by deuterium) of lubricating oils has been suggested to reduce the rate of oxidation of these materials. The effect is also of interest in biology. The fact that higher organisms cannot survive in environments of unusual isotopic abundances is due to the reduction in rates of some metabolically important reactions.

2.2.3. Bonding Effects

Variations in isotopic composition also influence chemical bonding and crystal structure [17, p. 15]. Although these effects are mass related to some extent (because vibrational bond frequencies are involved), the ionic nature of the counterion in some compounds appears to be the most important factor in determining the preference for one isotope over another in a specific bonding situation; the degree of order in the crystal structure plays a similar role in bulk solids. For example, the small, highly charged Si^{4+} cation has been found to be associated with a relatively higher ^{18}O concentration compared to other ionic species. Conversely, the larger Fe^{2+} cation is always found with a lower ^{18}O concentration than most other cations. Sulfur follows the same pattern, with the heavier ^{34}S associating more strongly with lighter, smaller cations such as Zn^{2+} as opposed to heavier cations such as Pb^{2+}. Crystal structure is of secondary importance to chemical bonding considerations, but definite trends can be cited in which the heavier of two isotopes is associated preferentially with more closely packed and well-ordered structures. Large effects may be noticed in specific cases, such as diamond and graphite, where the more ordered diamond crystal structure incorporates a higher fraction of ^{13}C than graphite.

2.3. Isotope Effects in Nature

The science of geochemistry has placed much emphasis on natural variations in isotopic abundance and the processes that cause fractionation of isotopes in geological and biological systems [18]. Many of the reaction mechanisms in these systems have been elucidated by studying the enrichment of a particular isotope and by theoretical calculations of the isotope effects associated with the system. Several generalizations can be made with respect to the natural variations of relative isotopic abundance. First, significant fractionation occurs only when relative mass differences between isotopes are large. Elements up to a mass number of ca. 40 exhibit measurable abundance variations, with only isolated examples at higher atomic mass. Second, equilibrium isotope effects are most important in geological systems, whereas kinetic effects predominate in biological systems, particularly in oxidation – reduction reactions. Third, the elements with the widest variations in isotopic composition are those that form compounds which are stable over a wide temperature range, because both equilibrium processes and kinetically controlled chemical reactions are temperature dependent. Also, elements that form compounds in different phases (solid, liquid, and gaseous) exhibit greater isotopic variations; in general, heavier isotopes exist in higher oxidation states in the solid state.

In geochemical studies, relative abundance is presented as the ratio of the amount of one isotope in a specific compound to the amount of that isotope in another compound. Measurement of absolute isotope abundance, a more difficult task, is very important because these values form the basis for calculations of the relative differences on a universal scale for each element [17, p. 23]. Values of absolute abundance are given as δ, in parts per thousand (‰), which compares the isotopic ratio of a sample with that of an accepted standard:

$$\delta\,(‰) = \frac{R_{\text{sample}} - R_{\text{standard}}}{R_{\text{standard}}} \times 1000 \qquad (12)$$

where R is the ratio of the abundance of the less common to the more common isotope. The primary standards, given in Table 5 for the more common elements, have been widely accepted. Although an individual laboratory may use its own internal standards for experimental work, values published in the literature are converted to the scale of one of these primary standards. In some cases (e.g., PDB for determining carbon isotope ratios), samples of the actual standard are no longer available and secondary standards are used based on the known ratio of the primary standard and produced by the National Bureau of Standards in the United States. The ranges of δ values given in the following examples are all referenced to primary standards.

Table 5. Worldwide standards in use for isotopic composition of some elements

Standard	Source	Isotope ratio	Value, ppm
SMOW (Standard Mean Ocean Water)	International Atomic Energy Agency	D/H	155.76
		$^{18}O/^{16}O$	2 005.20
		$^{17}O/^{16}O$	373
PDB	belemnite from Pee Dee formation, South Carolina	$^{13}C/^{12}C$	11 237.2
		$^{18}O/^{16}O$	2 067.1
		$^{17}O/^{16}O$	379
Air nitrogen	atmosphere	$^{15}N/^{14}N$	3 676.5
CDT	troilite from Canyon Diablo meteorite	$^{34}S/^{32}S$	45 004.5

Hydrogen shows large isotope effects. The range of D/H ratios is broadest in water trapped in meteorites, with δ values from +50 to -450 ‰ relative to Standard Mean Ocean Water (SMOW). Water on Earth varies between 0 and -80 ‰. Vapor-pressure and freezing-point differences between ordinary water and heavy water result in an increase of deuterium concentration in ice in the liquid – solid system, and in water in the vapor – liquid system. Equilibrium exchange reactions lead to significant enrichment of deuterium in the water vapor – methane, water vapor – hydrogen, and water vapor – hydrogen sulfide systems. Hydrous minerals also show isotope effects; δ values for sedimentary and igneous rocks on Earth lie in the range of -20 to -150 ‰. These systems are very complicated in their behavior. More than one type of chemically reactive site is usually present in these materials, and the effects of temperature and the presence or absence of water can contribute differently to the overall isotope fractionation. The isotope fractionation factor is defined as the D/H ratio in one substance divided by the D/H ratio in another. Figure 7 shows how the D/H isotope fractionation factor α^{D} changes with temperature in hydrated-mineral – water systems. Some clays and minerals act as semipermeable membranes to the passage of water, an effect known as *ultrafiltration,* and can cause enrichment of deuterium in the residual water because of their preference for absorbing the heavier isotope. Fractionation can also occur between the water in the hydration sphere of a mineral and the bulk water surrounding it. Biological systems are also involved in isotope enrichment. Hydrogen and methane produced as metabolic byproducts in some bacteria are enriched in the light isotope of hydrogen by a factor of up to 6, compared with that expected in the normal hydrogen – water system.

Figure 7. Isotope fractionation vs. temperature for some minerals
a) Muscovite; b) Serpentine; c) Phlogopite; d) Tremolite; e) Hornblende (B); f) Hornblende (A); g) Epidote – Chinozoisite; h) Actinolite; i) Biotite; j) Zoisite; k) Boehmite

Oxygen is also fractionated by equilibrium effects in many of these systems. Because of the smaller mass difference between oxygen isotopes, the range of δ values is smaller than that of hydrogen. In meteoric waters, the range for $^{18}O/^{16}O$ is + 10 to – 40 ‰ (relative to SMOW). The heavy isotopes are concentrated in two-phase water systems and hydration sphere – bulk water systems in the same manner as deuterium. Abundance ratios in rocks vary between + 40 and -5 ‰. Bond strengths play an important role in the fractionation of ^{18}O between minerals, as in the previous examples of silicon and iron. When a small quantity of water is in contact with a large amount of rock, the ^{18}O concentration in the water increases. However, when a small quantity of rock is in contact with a large

amount of water, the ^{18}O concentration of the rock increases. Kinetic isotope effects are evident in other oxygen-containing systems. The concentration of ^{18}O in the atmosphere cannot be explained by a simple equilibrium between oxygen in air and water. Photosynthesis results in enrichment of ^{18}O in the oxygen produced, when compared to the water from which it is derived. Respiration by plants and animals returns oxygen to the atmosphere with a higher ^{18}O concentration than that taken in.

Carbon is found on Earth in two major reservoirs: organic matter and sedimentary carbonates. In organic compounds, fractionation results in the enrichment of ^{12}C, with $^{13}C/^{12}C$ ratios ranging from -5 to -35 ‰, relative to the Belemnitella (PDB) standard; the figures are higher in this range for marine organisms and lower for sedimentary organic materials (e.g., petroleum). Kinetic isotope effects are also found in photosynthesis. The lighter isotope of carbon, ^{12}C, is concentrated in organic matter, and thus depleted in atmospheric carbon dioxide, in a two-step process. The uptake and diffusion of carbon dioxide are subject to a reversible equilibrium effect which produces a small enrichment of ^{12}C. The first carbon-dioxide-fixing carboxylation reaction of the photosynthesis sequence is an irreversible reaction with a large enrichment factor. As is typical in biological systems, the reaction rate is faster for molecules with lighter isotopes than for those with heavier isotopes. The geological form of carbon is enriched in ^{13}C mainly as a result of the equilibrium isotope effects in the $CaCO_3-CO_2-H_2O$ system:

$$Ca^{2+} + 2\,HCO_3^- \rightleftharpoons CaCO_3 + H_2O + CO_2 \qquad (13)$$

Some enrichment occurs as a result of the hydration and dehydration of carbon dioxide, but the major fractionation reaction is the precipitation of calcium carbonate; δ values between +5 and -15 ‰ are found. Kinetic effects are also seen in supersaturated solutions when equilibration does not take place between solid and solution before precipitation. Interactions between the organic and carbonate reservoirs allow a wide variety of isotope ratios to be found in nature.

Most of the nitrogen (>99 %) found on Earth is in the atmosphere in the form of molecular nitrogen (N_2) and has an essentially constant composition. Many biochemical reactions involving nitrogen (e.g., fixation, nitrification, and denitrification) have a small fractionation factor which results in an increase in the concentration of ^{15}N in organic materials. Nitrogen associated with natural gas deposits has been shown to have been depleted in ^{15}N by diffusional migration, the depletion increasing with increasing migration distance. The widest range of abundance ratios for nitrogen on earth is found in natural gas samples, with δ values from +30 to -25 ‰.

Kinetic isotope effects are significant in the absorption of boron compounds by clay minerals; ^{10}B is enriched by this process. Samples of sulfur compounds have been found to vary by as much as 150 ‰. Sulfur is enriched in ^{32}S by bacterial reduction of sulfates to hydrogen sulfide, for which kinetic effects are prominent. Ultrafiltration also results in fractionation because ^{32}S is absorbed into clays at a higher concentration than the heavier isotopes.

Natural exchange reactions and chemical bonding effects are found in a range of metallic sulfides; as with oxygen, the heavier isotopes of sulfur are associated preferentially with smaller, lighter cations. Selenium is also fractionated by bacterial reduction of selenates because compounds containing ^{76}Se are reduced faster than those containing ^{82}Se. Silicon shows very small effects (a range of ca. 6 ‰) since it is almost exclusively associated with oxygen in silicates and does not undergo oxidation–reduction reactions. Also, no gaseous and few liquid silicon compounds occur naturally. Chlorine is fractionated by equilibrium processes, mainly diffusion of liquid and gaseous compounds, resulting in enrichment of ^{35}Cl as a function of distance. Calcium shows very small equilibrium effects and no differences between geological and biological systems.

3. Uses of Isotopes

The differences in physical and chemical properties of individual isotopes are the basis for many applications. Isotopes of naturally occuring radioactive elements were first exploited for military purposes. Later, the principles of atomic energy were used to generate electricity and provide power plants for ships. Uses were also

found for a variety of isotopes in research. The discovery of methods for monitoring nuclear magnetic properties provided powerful tools for molecular analysis. The availability of quantities of separated or enriched isotopes allowed isotopic substitution studies of structures and mechanisms in chemistry. Physicists used the specific properties of individual isotopes to study nuclear phenomena and to detect cosmological events. In addition to research, applications have broadened to include medical and industrial uses. Radioactive isotopes are employed in the treatment of diseases, most notably cancer. Stable isotopes are used as precursors of the radioactive agents or as tracers in diagnosis. Many industrial uses of isotopes are in the developmental or limited-use stage. Promising techniques include isotopic tracing of products and waste materials. Environmentally, isotopes may be used to track the movement of pollutants and in hydrogeological investigations.

3.1. Nuclear Energy (→ Nuclear Technology)

In the late 1930s researchers discovered that naturally occurring uranium may undergo radioactive decay by fission, either spontaneously or induced by neutron capture. Fission is a nuclear transformation in which the nucleus splits into two relatively massive nuclei while emitting one or more neutrons. Fission is accompanied by release of a large amount of energy. All nuclides with mass number higher than 230 undergo fission reactions with half-lives that decrease with increasing mass number. Approximately 250 different species have been identified as fission products of uranium, and the average energy released is 195 MeV per atom. Self-sustaining chain reactions can be initiated if at least one neutron produced in a fission reaction induces decay of another atom.

The first use of fissile isotopes was in the construction of atomic bombs in the Manhattan Project during World War II [24]. Shortly thereafter, methods were developed to use the tremendous heat and pressure developed by atomic explosions as triggers for fusion, or thermonuclear, devices. Fusion reactions involve combination of light nuclei to form heavier species with release of even larger quantities of energy per atom than fission reactions. Specific isotopes are also important in fusion reactions. One of the most accessible fusion reaction (i.e., requiring the lowest temperature and pressure) is combination of deuterium and tritium. Tritium occurs only in trace amounts on Earth, but may be synthesized from ^{6}Li by neutron capture ($^{6}\mathrm{Li} + \mathrm{n} \rightarrow {}^{4}\mathrm{He} + {}^{3}\mathrm{H}$). A ^{6}Li-containing target is irradiated in a nuclear reactor or an accelerator to produce tritium, which is then extracted from the target. Lithium deuteride $^{6}\mathrm{Li}^{2}\mathrm{H}$ has been suggested as a fuel for fusion weapons as well [25]. A fission trigger creates an intense neutron flux that converts the Li to tritium, which fuses with the deuterium.

Fission reactions in nuclear weapons are uncontrolled, but by limiting the extent of the reaction this energy source can be harnessed in nuclear reactors for useful purposes such as generating electricity or providing high neutron fluxes for research and the production of valuable radioactive isotopes. Here again, the nuclear properties of specific nuclides are exploited. To sustain a controlled chain reaction, the energy of neutrons produced by fission must be reduced through collisions with other nuclei, a process called moderation. A good moderator has a mass close to that of the neutron to maximize energy loss per collision and a very small neutron capture cross section to minimize unwanted nuclear reactions. Deuterium is by far the best moderator; more than 80 times better than hydrogen and 30 times better than ^{12}C or ^{18}O [26]. Heavy water ($^{2}\mathrm{H}_2\mathrm{O}$) is almost as good as deuterium and has the distinct advantage of being a nonflammable liquid. Heavy water is also an excellent neutron reflector, and thus decreases the number of neutrons that escape the reactor core without participating in fission reactions. For fine control of reactor operations, neutron-absorbing isotopes are used to adjust the number of moderated neutrons available for inducing fission. Species with high thermal neutron capture cross sections include ^{10}B and ^{113}Cd. Other isotopes with very small cross sections are used to clad the nuclear fuel to protect it from the harsh environment in the reactor. Aluminum, a mononuclidic element, is widely used for this purpose.

3.2. Research

3.2.1. Nuclear Magnetic Resonance

Nuclear magnetic resonance (NMR) spectroscopy was discovered in 1946 by PURCELL and BLOCH [27]. In addition to the charge on the nucleus, about half of the naturally occurring nuclei possess spin angular momentum I as a result of the composition of the nucleus. Those nuclei with an even number of both protons and neutrons have a nuclear spin of zero. Other even atomic mass number nuclei with an odd number of both protons and neutrons (the only stable nuclides in this category are ^{2}H, ^{6}Li, ^{10}B, and ^{14}N) have integral spins (1, 2, 3, etc.). Nuclei with odd atomic mass numbers have half-integral spins (1/2, 3/2, 5/2, etc.). The multiplicity of the spin is determined by the *nuclear quadropole moment,* a measure of the charge distribution in the nucleus, and increases as the charge distribution deviates from spherical symmetry. The spinning charged nucleus generates a magnetic field and, therefore, has a magnetic moment m which is different for each nuclide. Table 6 lists some nuclides with nonzero nuclear spin and includes the magnetic moments of such species.

Nuclear magnetic resonance spectroscopy (see → Nuclear Magnetic Resonance and Electron Spin Spectroscopy) is based on the fact that the magnetic field generated by the nucleus is influenced by an external magnetic field. A distribution of allowed orientations with respect to the external field occurs in a group of the same nuclei. Changes in the distribution can be induced by an external radio-frequency energy input and monitored. The frequency causing a change in the distribution is called the *resonance frequency.* Because of the different magnetic moments possessed by different nuclides, the combination of magnetic field strength and radio-frequency energy may be varied to influence and monitor specific nuclides. Most often, frequency is held constant and magnetic field strength is varied to produce an NMR spectrum. The usefulness of this technique comes from its ability to detect subtle changes in the magnetic moment of a nucleus, and thus the resonance frequency, that are caused by the local electron environment in which the nucleus is found and its interaction with other nuclei in the vicinity. The difference between the resonance of any particular nucleus and that of a nucleus in a standard reference compound is referred to as the *chemical shift. Coupling,* interaction of the magnetic moments of two or more nuclei, is transmitted through the electrons that make up the chemical bonds between atoms and results in splitting the single resonance into more than one signal. The magnitude of splitting is called the *coupling constant.* The multiplicity of splitting is a result of the number of equivalent nuclei that interact with a given nucleus and their spins. A particular resonance signal may be split repeatedly by nonequivalent nuclei.

Table 6. Some stable nuclides with nonzero nuclear spin

Nuclide	Spin (I)	Magnetic moment, μ_N*
^{1}H	1/2	+2.793
^{2}H	1	+0.857
^{6}Li	1	+0.822
^{7}Li	3/2	+3.256
^{9}Be	3/2	−1.178
^{10}B	3	+1.801
^{11}B	3/2	+2.689
^{13}C	1/2	+0.702
^{14}N	1	+0.404
^{15}N	1/2	−0.283
^{17}O	5/2	−1.884
^{19}F	1	+2.629
^{23}Na	3/2	+2.218
^{25}Mg	5/2	−0.855
^{27}Al	5/2	+3.642
^{29}Si	1/2	−0.555
^{31}P	1/2	+1.132
^{33}S	3/2	+0.644
^{35}Cl	3/2	+0.822
^{45}Sc	7/2	+4.756
^{51}V	7/2	+5.151
^{55}Mn	5/2	+3.469
^{69}Ga	3/2	+2.017
^{73}Ge	9/2	−0.879
^{81}Br	3/2	+2.271
^{89}Y	1/2	−0.137
^{105}Pd	5/2	−0.642
^{107}Ag	1/2	−0.113
^{183}W	1/2	+0.118
^{195}Pt	1/2	+0.609
^{197}Au	3/2	+0.146
^{207}Pb	1/2	+0.593
^{235}U	7/2	−0.35

* The magnetic moment is given in nuclear magnetons $\mu_N = eh/2m_p$, where m_p is the proton rest mass

The first and still most widely used application for NMR spectroscopy is to investigate the spectra of ^{1}H in organic chemical analysis. The different proton environments in a molecule can be determined from the chemical shifts ob-

tained in a spectrum (e.g., protons of a methyl group, amino protons, etc). The splitting patterns and coupling constants give information about the arrangement of different environments, i.e., what groups are adjacent to each other. By determining the area of various signals, the ratio of protons in various environments can be determined. The wealth of information available from a NMR spectrum makes it a powerful tool for determining the presence of known materials and identifying the structure of newly synthesized compounds. An example of the latter is confirmation of the structure of dodecahedrane, which was first synthesized in 1985 in a 28-step procedure [28]. The NMR spectrum gave a single sharp peak indicating that the hydrogen atoms at each of the 20 vertices of the molecule are all in equivalent environments, expected for a symmetrical structure.

In addition to qualitative uses, ^{1}H NMR is also valuable for quantitative analysis because of the direct relationship between resonance peak area and relative proton abundance. For example, the purity of epoxy monomers can be calculated by comparing the area of the signal from the methylene protons of the glycidyl group with that of the signal from the proton attached directly to the adjacent carbon on the oxirane ring [29]. Similarly, the chain length of oligomeric compounds may be determined by measuring the ratio of protons in the repeating units to those of the end groups.

Nuclear magnetic resonance spectroscopy is applied more universally than merely to compounds containing hydrogen, and many other nuclei are used routinely with this technique. Mononuclidic elements with nuclear spin 1/2 and large magnetic moments are the species of choice to avoid isotopic interference, simplify spectra, and provide large separations in chemical shifts for different nuclear environments. Much of the chemistry of ^{31}P and ^{19}F has been determined with the help of NMR. Evidence for the *Berry mechanism of pseudorotation* in molecules with trigonal – bipyramidal configuration, important in the chemistry of phosphorus, was obtained from NMR spectra [30].

Other nuclei that are often used for NMR spectroscopy include ^{11}B, ^{13}C, ^{29}Si, and ^{195}Pt. Such species introduce complexities into the experimental technique because of low natural abundance, small magnetic moments, or large quadropole effects, but they can give valuable chemical information not obtainable by other means. Although ^{13}C NMR is an important adjunct to ^{1}H NMR in organic chemical analysis, it suffers from both the low abundance (1.11 %) and the small magnetic moment (ca. 25 % that of the proton) of ^{13}C.

3.2.2. Electron Spin Resonance

An unpaired electron possessing a spin of 1/2 has a magnetic moment that responds to a magnetic field in the same way as a nucleus (see Section 3.2.1). Electron spin resonance (ESR; sometimes called electron paramagnetic resonance, EPR) is a spectroscopic method that detects the transitions between energy levels created by interaction of the electron spin with a magnetic field. Stable radical species, certain electronic energy states, and ions and compounds of transition metals and rare-earth elements with unpaired electrons can be analyzed by this technique. Electron spin resonance was first employed in the analysis of organic radical species, but its use has been extended to include quantitative determination of ions such as vanadium(IV), manganese(II), copper(II), chromium(III), gadolinium(III), iron(III), and titanium(III) [14, p. 236].

Isotopes play a role in ESR spectroscopy because the signal from an unpaired electron is affected by the magnetic moments of nuclei contained in the radical molecule or associated with the metal ion containing the unpaired electron. The magnetic moment of an atom with a nonzero nuclear spin couples with the magnetic moment of the electron, called *hyperfine interaction,* to split the resonance signal of the electron into more than one peak. The value of the nuclear spin and the number of interacting nuclei determine the multiplicity of ESR signal splitting. Analysis of hyperfine splitting aids in determining the molecular structure and the nature of the unpaired electron, e.g., whether it is localized on one atom or delocalized over part or all of the molecule.

3.2.3. Mössbauer Spectroscopy

Nuclear gamma-ray resonance spectroscopy, better known as *Mössbauer spectroscopy,* is a

radiochemical analysis technique that relies on the ability of certain nuclides to absorb and emit gamma rays without loss of energy when tightly bound in a crystal lattice [5, p. 185]. Gamma-ray photons originate from a source outside the sample and are absorbed by nuclides in the sample that have the same electronic configuration, and thus the same transition energies, as the source; the two nuclides are then said to be in *resonance.* The absorbed photons are then reemitted, and the apparatus detects both the reduction in number of photons from the source and the reemitted photons. A different electronic configuration of the nuclide in the crystal results in different transition energies and does not allow resonance. The energy of gamma radiation from the source may be altered by *doppler shifting* of the source (i.e., by moving it toward or away from the sample to increase or decrease the photon energy, respectively). A scan over a range of velocities reveals the particular point at which resonance is established. The difference in energy between the source and the target is called the *isomer shift,* and is measured in cm/s relative to a standard such as stainless steel. Signal splitting arises when the quadrupole moment of the nucleus being examined is nonzero, because the resulting electric field gradient interacts with the electron cloud around the nucleus. Thus, splitting provides information about the chemical bonding, oxidation state, crystal lattice, and other features that affect electron distribution.

The Mössbauer effect has been observed in ca. 50 nuclides, with the most widely used isotopes being ^{57}Fe (2.1 % abundance) and ^{119}Sn (8.6 % abundance). The ^{57}Fe is produced from radioactive ^{57}Co ($t_{1/2} = 270$ d) which decays by electron capture to an excited metastable state ^{57m}Fe. The excited state is transformed to either the ground state of ^{57}Fe or an isomeric metastable form of ^{57m}Fe by emission of gamma photons. The isomeric form also decays to the ground state with the emission of gamma rays that are the source for Mössbauer spectroscopy of ^{57}Fe compounds. An example of the use of this technique is the investigation of iron cyanates, which showed that Prussian blue, formed from Fe^{3+} and $Fe(CN)_6^{4-}$, and Turnbull's blue, from Fe^{2+} and $Fe(CN)_6^{3-}$, both have the composition $Fe_4[Fe(CN]_6]_3$ [31]. In addition, high-spin iron(III) with five unpaired d-electrons and low-spin Fe(II) with six paired d-electrons were each identified in the compound, indicating that the individual iron atoms have distinct electron environments.

3.2.4. Isotopic Substitution

Property differences among isotopes of an element can be used in conjunction with other analytical techniques to determine chemical mechanisms, molecular structure, and various phenomena of interest. Because the isotopes of most elements do not differ significantly in their chemical properties, isotopes may be interchanged in a molecule and physical differences (e.g., mass or nuclear spin) can be exploited to highlight specific features by NMR, microwave, mass spectroscopy, or other analytical methods. This technique is especially valuable when applied to elements with one overwhelmingly abundant isotope.

Isotopic substitution can be used to determine chemical mechanisms. The mechanism of alkaline hydrolysis of esters has been elucidated by synthesizing materials with ^{18}O in specific sites (*isotopic labeling*) and following the reactions involving those sites [32]. By labeling the alkoxy oxygen of an ester, cleavage of the ester to the alcohol was shown to occur between that oxygen and the acyl group. Analyses in these investigations were made by mass spectroscopy and identification of the species with which the higher mass oxygen isotope was associated.

Structural determination is also aided by isotopic substitution. Isotopes introduced into specific sites allow identification of the atomic arrangement in molecules. One of the most widespread methods employs deuterium substitution in ^{1}H-NMR studies. In these cases, the desired result is obtained not by monitoring deuterium but by seeing what effect the absence of a proton at selected sites has on the ^{1}H spectra. Specific resonances disappear or are reduced in intensity, and signal splitting multiplicities and coupling constants change as a result of the presence of deuterium. Other spectroscopic investigations also benefit from isotopic substitution. An example is the first reported isolation of the primary ozonide of ethylene [33]. The short-lived species was generated in the cavity of a microwave spec-

trometer at low temperature and was identified as the initial product of the combination of ozone and ethylene, but its structure could not be determined unambiguously. By substituting ethylene that contained deuterium and ^{13}C for ordinary ethylene and repeating the experiments, additional information obtained from changes in the mass of the constituent atoms allowed calculation of bond angles and lengths. From this information, the position of the atoms could be determined. Other types of reactions and chemical systems studied include molecular rearrangements, enzyme-catalyzed reactions, and solvolytic nucleophilic reactions [34].

3.2.5. Cosmology

Many other areas of science in addition to chemistry take advantage of the unique properties of specific isotopes. In the field of cosmology the investigation of solar neutrinos produced in fusion reactions in the sun relies on neutrino interactions with certain isotopes. One of the first studies involved the use of chlorine, in the form of a large quantity of carbon tetrachloride. Neutrinos induce a nuclear reaction in ^{37}Cl which converts it to ^{37}Ar, whose β emission can be readily monitored. These studies showed that the number of events caused by neutrinos was only about one-third of that predicted by the best theoretical models of the sun [35]. The ^{37}Cl detector, however, is sensitive only to neutrinos with energy above a certain threshold and not to those produced by the fusion of two hydrogen nuclei, the most common solar nuclear reaction. More recent experiments have been conducted with other isotopes sensitive to a wider spectrum of neutrino energies [34]. The GALLAX detector, operated between 1991 and 1997, used 100 t of gallium chloride containing about 12 t of ^{71}Ga. Reaction of this isotope with neutrinos produces radioactive ^{71}Ge, which was extracted as the volatile germanium chloride and converted to the hydride, GeH_4, and its decay measured. A typical run lasted six months and detected 25 neutrino interactions [36]. The Sudbury Neutrino Observatory used 1000 t of heavy water, 99.92 % isotopically enriched deuterium oxide. This detector was sensitive to the low-energy neutrinos resulting from the production of ^{8}B in the sun. The information from these and other experiments reinforced the initial conclusion that the neutrino flux is less than predicted by the standard solar model. A number of theories have been put forth to explain the results, but none has yet received widespread acceptance.

3.2.6. Nuclear Science

Nuclear physicists have employed specific isotopes to make the first observations of an extremely rare form of radioactive decay, the simultaneous emission of two beta particles. Double-beta decay was predicted in the 1930s as a method for decay of unstable nuclides that were prohibited from undergoing simple beta decay because of binding-energy considerations (→ Radionuclides, Chap. 1.3.). A number of very sensitive, long-term experiments have been conducted to study this phenomenon [37]. The first attempts to identify double-beta decay involved geochemical analysis of tellurium- and selenium-containing ores to measure the amounts and isotopic ratios of noble gases trapped in the ores. The nuclides ^{130}Xe, ^{128}Xe, and ^{82}Kr are the daughter products of double-beta decay of ^{130}Te, ^{128}Te, and ^{82}Se, respectively. The results gave evidence for this type of nuclear decay and estimated the half-lives to be 10^{19} a or greater. However, these studies could not determine which of the theoretical decay modes was involved. Attempts to observe the phenomenon in the laboratory have employed ^{76}Ge, ^{100}Mo, and ^{136}Xe. These experiments have been able to detect the decay process that produces two neutrinos but only estimate a lower limit for the neutrinoless mode. The latter is of particular interest to physicists since, if it actually exists, it will help to establish a mass for the neutrino.

3.2.7. Materials Science

Positron spectroscopy has been applied with great success to materials science [38]. The technique is based on the fact that certain radioactive species decay by conversion of a proton to a neutron accompanied by emission of a positron, the anti-matter counterpart of the electron. Positron lifetimes are very short (ca. 10^{-10} s). When a positron encounters an electron both particles are annihilated and energy

is produced, usually in the form of two γ-rays. Positron spectroscopy is the detection and measurement of these γ-rays. This decay mode is typical of unstable nuclides that are proton-rich. Such species can be produced in cyclotrons, in which stable isotope targets are bombarded with charged particles, protons, or deuterons, or in nuclear reactors or other devices, where neutrons are the bombarding species. The process of adding particles to stable nuclides is called activation (→ Radionuclides, Chap. 3.). Stable-isotope precursors of positron-emitting species for materials science uses include ^{63}Cu, used to produce ^{64}Cu (n, γ reaction); ^{79}Br to produce ^{79}Kr (p, n reaction); ^{58}Ni to produce ^{58}Co (p, n); and ^{22}Ne to produce ^{22}Na (p, n).

Attributes of positron spectroscopy that make it a useful analysis technique include its ability to provide depth-profiling and its nondestructive nature. When a positron is introduced into a material it has a tendency to localize at regions of relative negative potential such as vacancies and voids. Upon annihilation, the photons produced easily escape from the material, and their signature is directly related to local environment around the positron when it reacted with an electron. Early uses of the method were limited to investigation of simple metals such as copper and aluminum for detection of point defects in metal lattices. The technique has been extended to study the effects of annealing, work hardening, and radiation damage in metals and alloys, as well as investigating free volume effects in polymers. With the advent of slow positron sources, positron spectroscopy has become a valuable tool in study of silicon-based electronic devices, especially the various methods for their manufacture and the interactions at the interfaces between the different materials that constitute such devices.

3.2.8. Ecological Research

Stable isotope analysis can be applied to ecological research to investigate processes within and between organisms and between organisms and their environment [39–42]. Isotope ratios were first used in the 1970s by geochemists in analysis of fossil plant matter to elucidate climate and climatic changes during the period when the plants lived. Hydrogen isotope ratios were analyzed in peat samples and in annual growth rings of treas and correlated to temperature. The initial studies included the simplifying assumption that the hydrogen isotope ratios in plants were only affected by the ratios in the water available, which is a function of temperature. Several sources of error were identified in these studies, including the fact that cellulose contains hydroxyl hydrogen atoms that are easily exchangeable. Hence, the measured hydrogen ratio is influenced by the last water to which the cellulose was exposed, which may have been in sample preparation. In addition, different substances within the same plant may have different isotope ratios as a result of the specific biological processes they undergo. Whole plant sampling gives an overall ratio that is affected by the relative amounts of the various constituents. The procedures now used for climatic studies involving plant matter minimize these errors and better reflect environmental differences. Recognition of the possible artifacts affecting climatic studies were a catalyst for investigation of a wide range of physiological processes in plants, by using stable isotope analysis. The greater availability of isotope-ratio mass spectrometers also made such studies more common.

Carbon isotope ratios have been used to study the differences in photosynthesis pathways of plants. The primary carboxylase enzymes involved in fixation of carbon dioxide from the air by the C_3 and C_4 pathways have different kinetic isotope effects and thus result in different δ (^{13}C) values in plant matter. The C_3 pathway typically results in a value of about -27 ‰ and the C_4 pathway -12 ‰. δ (^{13}C) values in soil are also affected when C_3 crops replace C_4 crops (or vice versa), whereby different types of soil and different particle sizes exhibiting different replacement times. Fine clay appears to be the "youngest" part of a soil mixture.

Studies of carbon isotope ratios have also been used to measure the efficiency of water use by plants. The rate of CO_2 assimilation by plants is proportional to the rate of water loss, since both are a function of the diffusion of gases through plant membranes such as leaves. Since diffusion of $^{13}CO_2$ is slower than that of $^{12}CO_2$ because of the greater mass of the former, a carbon isotope ratio in the plant that is closer to that of the atmosphere indicates less diffusion of CO_2 into the plant and implies less water loss, i.e.,

greater water efficiency. The same techniques have been used to study the response of plants to various environmental stresses such as water availability and salinity, light flux, and temperature.

While carbon dioxide is essentially the only source of carbon for photosynthesis in plants, there are three potential sources of oxygen: carbon dioxide, molecular oxygen from air, and water. Plants grown in atmospheres containing CO_2 with greatly different ^{18}O content, but the same water, did not show significant differences in oxygen isotope ratios. Effects that may arise from molecular oxygen during photorespiration appear to be lost during subsequent steps in the photosynthesis. These results, coupled with other more direct experiments, indicate that water is the only significant source of differences in oxygen isotope ratios, and that the δ (^{18}O) value in plants is consistently about +27 ‰ greater that of water. Mechanistic studies point to the carbonyl hydration reaction at the three-carbon-sugar level as the overriding step in photosynthesis that determines the oxygen isotope ratio. The same degree of enrichment also occurs in the simplest chemical system analogous to this reaction, a δ (^{18}O) of +27 ‰ is found in the carbonyl oxygen of acetone in equilibrium with water.

The nitrogen cycle in terrestrial systems is complex, starting with N_2 from the atmosphere which is reduced (fixed) to ammonia by microorganisms in the soil or in the commercial production of fertilizers involving the Haber Process. Ammonia or the ammonium ion can be directly assimilated by plants or oxidized to nitrate by other soil bacteria and absorbed in that form. Studies of nitrogen-fixing plants have used analysis of variations in the natural isotope abundance of nitrogen very effectively. Other experimental work has employed materials artificially depleted in ^{15}N, including fertilizers. Assessment of the effects of different methods of soil preparation showed that nitrogen uptake from fertilizer was approximately the same in all cases, but the total nitrogen was greater in the plants grown in soil that had been disturbed the least in preparation. This suggested that microbial activity converting nitrogen to a form usable by the plants was greater when the soil was not tilled. Depleted fertilizer was also used in a study of the ability of various plant residues, when returned to the soil, to provide nitrogen to the next generation of crops. Soybeans were found to be a good source of nitrogen that could be utilized by plants, whereas corn was not.

In many cases it is essential to analyze the isotopic composition of more than one element to draw the correct conclusions. Studies of the generation and destruction of methane by microorganisms in sediments included analysis of both carbon and hydrogen isotopes. Because of a kinetic isotope effect, the methane produced is depleted in ^{13}C. The oxidation of methane also has an isotope-fractionation factor, in this case leaving the CH_4 enriched in ^{13}C. In one study, δ (^{13}C) values of methane were measured as a function of depth in sediment samples to determine where the various processes were occurring. The results indicated that methane production occurred throughout the sediment, while oxidation occurred only in a narrow zone. Analysis of the δ (^{2}H) values confirmed that the differences in ^{13}C concentration were a result of the oxidation of methane and not an artifact of the different diffusion rates through the soil expected for the various isotopic combinations of carbon and hydrogen making up the methane.

Strontium isotopic analysis has been used to study large ecological systems. Analysis of trees in a northern New Mexico watershed allowed determination of the percentages of the biomass that were derived from weathering of the bedrock versus the amount derived from atmospheric input. An unexpected benefit from this study was recognition that the method could also be used to estimate the depth of the rooting zone of the trees.

Environmental studies have been performed by using analysis of sulfur and nitrogen isotopes. Oxides of sulfur and nitrogen are emitted from fossil fuel burning power plants and other air pollution sources in large quantities and affect large areas in industrialized countries. Studies were carried out, beginning in the 1970s, of the effect of SO_2 on ecosystems in areas around natural gas refineries in Canada. A number of factors made these sites ideal for such investigations. The SO_2 contained in the natural gas that was removed during the refining process had a δ (^{34}S) that was significantly different from the background values in surrounding soil (as much as +15 ‰). There were few other potential environmental pollutants, such as heavy

metals, and the refinery locations were separated such that each acted as a point source. Initial studies looked at the distribution of sulfur in the surrounding areas and found the highest sulfur and, particularly ^{34}S, concentrations downwind from the refineries, and the lowest concentration upwind. The composition of plant life was also different, but the cause and effect relationship to the presence of SO_2 could only be inferred. To examine the accumulation of sulfur in plants and the metabolic effects, SO_2 enriched in ^{34}S has been used. Plants exposed to high levels of labeled SO_2 show increased levels of sulfates, sulfur-containing amino acids, and other sulfur containing compounds. δ (^{34}S) values in all of these compounds were found to be higher than in control samples, and the indicated atmospheric sulfur as the source.

Methane is a very efficient greenhouse gas, and its concentration has been increasing at about 1 % per year in the atmosphere. Analyses of ice core samples suggest this increase began in the 1700s and accelerated in the twentieth century. Methane has a residence time in the atmosphere of about nine years and is chiefly removed by reaction with hydroxyl radicals. There is great interest in determining the contributions of the numerous sources of the gas. Atmospheric methane has a δ (^{13}C) of -47.7 ‰. Analysis of the δ (^{13}C) values of its sources, allows estimations of the importance of their contributions to the approximately 600×10^6 of methane entering the atmosphere annually. Wetland and tundra soils are estimated to contribute about 25 % of the annual methane production. Natural gas production and fossil fuel burning contribute another 25 % and rice cultivation a similar amount. Physiological processes in ruminants and biomass burning are other major sources. These estimates include rather large uncertainties because of the range of δ (^{13}C) values found for each of the source categories, including seasonal variations in the same source.

Another isotope that is valuable for environmental studies is ^{14}C, a naturally occurring radioactive isotope that is produced in trace amounts in the atmosphere by cosmic rays interacting with ^{14}N (p, n reaction). It enters the biosphere from the air and has been extensively used in dating of materials. Because of its short half-life ($t_{1/2} = 5730$ years) ^{14}C is essentially absent from long-sequestered sources of carbon like fossil fuels, and these are known as "dead" carbon. Measurement of ^{14}C in the atmosphere during the 20th century shows a decrease in δ (^{14}C) from the early 1900s to the mid 1950s, as the burning of fossil fuels added large amounts of CO_2 to air that contained little of the radioactive isotope. A large increase in the ^{14}C concentration of the atmosphere occurred in the 1950s as a result of atmospheric testing of nuclear weapons. This source has caused problems with interpretations of radiocarbon dating experiments but has allowed a much greater understanding of the carbon cycle in the Earth. Bomb-produced ^{14}C has been used to verify residence times of gases in various layers of the atmosphere and to demonstrate that the mixing between surface and deep ocean waters is much slower than originally thought, taking hundreds to thousands of years.

3.2.9. Isotope Chronostratigraphy

A specialized area of geological research that is of potential commercial interest is isotope chronostratigraphy [43], the determination of when a layer of sedimentary rock was formed by analysis of the carbon and oxygen isotope ratios. The basis of this technology is studies of samples from the Deep Sea Drilling Project. Extensive analysis of these samples by a number of methods has given a remarkably detailed description of the oceanographic and biological history of the Earth during the Tertiary era, 65 to 2.8 million years ago. Values of δ (^{13}C) and δ (^{18}O) in carbonates from fossilized marine animals (benthic and planktonic foraminifera and coccoliths) from the DSDP samples have been correlated to the overall timeline. Variations in these values over time reflect changes in ocean chemistry. Parameters such as temperature, water depth, salinity and sources of carbon dioxide affect the δ values of both carbon and oxygen in marine carbonates, but not necessarily to the same extent for each element. For example, the oxygen ratio is affected to a much greater degree than the carbon ratio by temperature.

Extrapolation of the isotope ratio information from the well-characterized samples of the DSDP to other samples from exploratory drilling sites is of great interest to oil companies. Values of δ (^{13}C) and δ (^{18}O) and trends in their

changes versus drilling depth from new wells may be compared with the features of known petroleum-bearing layers to identify the potential for new wells to find untapped reserves. Isotope chronostratigraphy appears particularly suited to investigation of deep-water sites where formations resemble the DSDP drilling sites. Advances in the methodology include more sophisticated mathematical treatments to replace the original empirical analysis of results and the integration of isotope ratio information with other analysis techniques such as biostratigraphy and paleomagnetic stratigraphy. These innovations hold promise for broadening the applicability of the technology to a wide variety of sedimentary formations.

3.2.10. Anthropology

Isotope analysis of anthropological remains is one of many methods available for the study of diets of prehistoric peoples [44]. Information on food acquisition, consumption and distribution is typically very important in understanding ancient societies and their evolution. Carbon and nitrogen have been the most extensively analyzed elements in such studies, but others have been used as well. Collagen, the organic matrix in bone, contains carbon and nitrogen, and collagen residues are typically associated with skeletal remains. δ (^{13}C), and δ (^{15}N) values can be used to indicate aspects of ancient diets, especially differences in consumption of C_3 plants (rice, potatoes, wheat, etc.) versus C_4 plants (maize, sorghum, millet, etc.), and marine versus terrestrial food sources. Hydroxyapatite, the inorganic portion of bone that makes up the majority of the mass, contains carbon as carbonate, but its usefulness is complicated by exchange reactions with carbonate in groundwater. The technique of stable isotopic analysis has been applied to many surveys throughout the world, and the results have been helpful in determination of diet, changes in agricultural practices, food distribution, and domestication of animals.

Strontium is also useful in dietary investigations [45] as it is present in most rocks in small quantities and makes its way into the food chain as a substitute for calcium in certain minerals. The isotopic composition of strontium varies with rock type and geological age because one of its isotopes, ^{87}Sr, is a decay product of the naturally occurring radioactive isotope ^{87}Rb ($t_{1/2} = 4.9 \times 10^{10}$ years). Analysis of Sr isotopes has been extensively used in geological studies to date rock formations, and a large body of information is available about the isotopic distribution of Sr in many locations. A pilot study of strontium isotopic analysis in ecological investigations involved analysis of bones and teeth of prehistoric humans. The ^{87}Sr/^{86}Sr ratio in remains of two persons found in an ancient coastal village near what is now Los Angeles, California, were consistent with the strontium ratio in seawater and indicated a diet high in marine food. Remains from an inland village inhabited by people from the same tribe were found to have a lower ^{87}Sr/^{86}Sr ratio than the coastal remains, but higher than that of the soil in the area of village. The results were consistent with the known behavior of the tribe: inland villagers typically spent part of the year inland but moved to the coast during other parts of the year, where they ate fish. Carbon isotope analyses was consistent with the strontium results: a high-marine-food diet in the coastal villagers and lower amounts of marine food in the diet of the upland villagers. An interesting specific application of the strontium analysis technique would be to identify the remains of Christopher Columbus and his son, Don Diego, who are said to be buried together in the Cathedral of Santo Domingo in the Dominican Republic. The elder Columbus was a resident of Genoa, Italy, during his youth, while his son lived in Seville, Spain, as an adolescent. The strontium ratio in the soil from the two locations is sufficiently different that isotopic analysis of the teeth and bones of the remains should distinguish between these two historical figures.

3.3. Medical Uses

One of the fastest growing uses of isotopes is in medicine. New techniques exploit the special properties of particular isotopes for diagnostic work and employ stable isotopes as target materials to produce radioactive species for both diagnosis and treatment.

3.3.1. Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a medical diagnostic method that exploits the magnetic properties of certain nuclei [47] in the same way as NMR is used in chemical analysis (see Section 3.2.1). This technique is able to generate cross sections and three-dimensional images of the human body and to follow the progress of physiological functions that involve magnetically active nuclei. In NMR, the transitions between spin states of magnetic nuclei are monitored, and the frequency necessary to induce transitions as well as the intensity of the transitions are determined. Conversely, MRI monitors the rate of *relaxation* between spin states and the intensity of the transitions. Relaxation is the process by which the nucleus undergoes a transition from a higher energy spin state to a lower one. The energy difference between spin states depends on the strength of the applied magnetic field but is typically very small (ca. 0.01 eV), and is thus lower than the average thermal energy of atoms and molecules at room temperature. Therefore, the population of the two energy states can easily become saturated and equal numbers of nuclei in both states result in equal amounts of absorption and emission and, thus, no measurable signal. However, nuclei can interact with their surroundings and relax to the lower energy spin state by two mechanisms. In *spin – lattice relaxation,* the component of magnetization in the z direction (aligned with the external magnetic field) is returned to its equilibrium value; it is characterized by a relaxation time T_1. Relaxation occurs when nuclei interact with oscillating fields produced by neighboring magnetic nuclei which have the same frequency and phase as the excited nuclei. Many factors are involved in spin – lattice relaxation, including viscosity, temperature, and concentration. Interaction with the unpaired electrons of paramagnetic molecules, such as dissolved molecular oxygen in the sample, is a very effective mechanism for inducing spin – lattice relaxation. Nuclei with a quadropole moment may relax by interaction with their own electrons. Relaxation in the xy plane, perpendicular to the applied field, is called *spin – spin relaxation* and is characterized by a relaxation time T_2. Spin – spin relaxation is a function of the phase coherence of the excited nuclei and may be affected by the viscosity of the medium and spin – spin exchange reactions between excited nuclei.

Magnetic resonance imaging usually monitors protons, which are found in most biological substances. The specific environment of the nucleus, the molecule of which it is a part, and the molecules in its immediate vicinity determine the relaxation times T_1 and T_2. The number of protons of a particular type determines the intensity of the signal. With sophisticated computer control and signal analysis, MRI spectrometers collect data simultaneously from two perpendicular directions to generate cross-sectional images of the body. Combining successive cross sections develops a three-dimensional picture. The differences in relaxation times and intensities for the hydrogen nuclei in various tissues give remarkable definition to the images. Among others, tumors, aneurisms, and herniated disks can be diagnosed with this technique.

Although hydrogen is an excellent nucleus for providing well-defined images of soft tissue structures in the body, its ubiquity makes it less suitable for the study of physiological functions. For investigations of this type, the best technique is to introduce isotopically substituted compounds into the body and follow their pathways, concentration sites, and chemical reactivity. Ideally, a compound used in this manner will incorporate a magnetically active isotope in place of a nonactive isotope in a biologically important compound; for example, ^{13}C is frequently used to replace ^{12}C, and ^{17}O to replace ^{16}O. The metabolism of glucose in the brain of animals has been studied by following the chemical reactions of ^{13}C-labeled glucose [48]. Other nuclides, including ^{2}H, ^{7}Li, ^{23}Na, ^{35}Cl, and ^{87}Rb, are used in high magnetic fields ($>$10 T), rather than the 1.5 – 5-T fields routinely used for ^{1}H. The higher fields result in greater splitting and first-order spectra, which allow much more information to be obtained about metabolic functions [49]. For very precise measurements, the equilibrium and kinetic isotope effects of the substituted species (see Section 2.2) should be insignificant, or data should be corrected to reflect the different reactivity of the labeled compound. In addition to the direct study of metabolism with isotopically labeled materials, secondary effects may be used to obtain information. Changes in relaxation times are induced by isotopic composition changes of the

medium in which the targeted nucleus is found. For example, water incorporating ^{17}O induces relaxation in the hydrogen nucleus at a different rate than water containing ^{16}O. Advances in MRI include the use of contrast-enhancing agents, such as organic chelates of gadolinium, especially ^{153}Gd, to provide increased definition.

3.3.2. Stable Isotopes in Metabolic Studies

Stable-isotope analysis has been used in the study of human and animal metabolism. Studies of carbon isotope ratios in animals [50] shows a correlation between the overall δ (^{13}C) value in the body and the δ (^{13}C) value in the diet, with a slight enrichment of ^{13}C in the animal. As might be expected from similar findings in plants, individual tissue types differed in carbon isotope ratios. In gerbils, hair was enriched, and fat depleted, in ^{13}C from the diet, and the results were somewhat diet-dependent. Changes in δ (^{13}C) values in body tissues were noted when diets were altered in ^{13}C content (by switching from C_3 to C_4 plants). The tissue replacement half-lives could then be estimated: they range from 6.4 d for liver to 27.6 d for muscle.

Human metabolism of inorganic nutrients, including Fe, Zn, Mg, Cu, Se, and Ca, has been studied by using enriched stable isotopes [51]. Introduction of the labeled species can be intrinsic, through biological incorporation in food, or extrinsic, by mixing with food before consumption. Iron and zinc have most often been incorporated intrinsically. Peas, spinach, and wheat have been labeled during plant growth. Milk, eggs, and meat have been labeled by injecting animals with solutions of enriched isotopes. The uptake of nutrients may be calculated from the difference between the administered amount and the amount found in analysis of excreted materials. Other studies have measured isotopic abundance directly in blood plasma or hemoglobin. A double stable-isotope technique, analogous to that first developed with radioactive tracers, has been used in which two different enriched isotopes of the same element are simultaneously administered, orally and intravenously. Studies of calcium absorption have used oral dosing with ^{44}Ca-enriched foods and injection of ^{42}Ca-enriched solution. The ratio of the isotopes in plasma or urine after 24 h is measured to determine the metabolism of the element. Double-isotope studies with ^{67}Zn and ^{70}Zn have been performed to measure the normal loss of this nutrient from the body and allow more accurate calculation of absorption values.

Whole-body calorimetry, developed more than 100 years ago, measures energy requirements by enclosing a human subject for hours or days in a room that monitors heat loss and oxygen consumption. While allowing very accurate measurements, it hardly simulates a person's typical routine. In the 1950s another method for obtaining the same information was developed, the doubly labeled water technique which employs $^{2}H_2^{18}O$. Both isotopes reach equilibrium rapidly in the body, the deuterium through exchange reactions with water, and the oxygen with both water and carbon dioxide. Test subjects drink the labeled water or it is injected into the blood stream. The disappearance of the isotopes from the body is monitored by analysis of urine, blood, or saliva samples, during which time the person may goes about normal activities. Analysis of the deuterium concentration over time gives the water turnover rate. Analysis of the ^{18}O concentration gives the sum of the water and carbon dioxide turnover rates and, by difference, the carbon dioxide value. The CO_2 value is used in calorimetric calculations to determine the energy expenditure over the study period. Several assumptions must be made, including the relative quantities of fat and carbohydrates consumed and the amount of water lost through perspiration, but the precision of the method is estimated to be better than 5 %. A comparison with whole-body calorimetry over a 12-d period found them to agree within 2 %. The doubly labeled water method has been used in a large number of diverse biological investigations [52]. Specific studies in humans include metabolic correlation of obesity and activity, the effects of total intravenous feeding on adults, and metabolic processes of premature infants. In other species, it was one of the technique used in a field study of Galapagos marine iguanas that showed how these animals regulated osmotic balance in their bodies despite large intake of sea water. It also has been used to compare the energetic cost of flight in various types of birds, and to understand the behavioral characteristics of desert rodents that allows them to survive with-

out winter hibernation. Sufficient data has been gathered to allow predictive models to be created to describe energy and material flow though habitats and estimate field metabolic rates and food requirements for various species.

3.3.3. Stable Isotopes in Medical Diagnosis

A simple, accurate, noninvasive test that uses stable isotopes to identify a bacteria that causes stomach and intestinal ulcers has been approved by the U.S. FDA [53]. *Helicobacter pylori* infects epithelial cells throughout the digestive system in humans, producing ammonia and the ammonium ions to regulate the pH in its immediate vicinity and protect itself against normal stomach acidity. The most important enzyme in the bacteria's protective mechanism is urease, which hydrolyzes urea to form ammonia and carbon dioxide. The test uses ^{13}C-enriched urea, swallowed by the patient, and measurement of the ^{13}C content of carbon dioxide from a breath test taken about 30 min after ingestion of the labeled urea. Elevated levels of $^{13}CO_2$ in the exhaled gases, as compared to reference breath sample taken before the test, indicate infection by *H. pylori*. The test has been shown to be sensitive and specific for the bacteria and can be used in initial diagnosis and to determine if subsequent treatment is effective. The FDA has approved several companies to produce the labeled urea.

3.3.4. Stable Isotopes as Radioisotope Precursors

In addition to their use directly in diagnosis, stable isotopes are more prevalent as precursors to radioactive species used in both diagnosis and treatment. Positron emission tomography (PET) is a medical technique analogous to positron spectroscopy (see Section 3.2.7) that can produce three-dimensional images of the body or specific organs and can also be used to study physiological functions. Positron-emitting species for PET are typically low atomic mass elements that may be substituted for stable nuclides in biologically active compounds. These are routinely produced in cyclotrons by charged particle activation (→ Radionuclides) and include ^{11}C, ^{13}N, ^{15}O and ^{18}F. An extensive area of chemistry has developed around production of PET-useful compounds incorporating these short-half life species. Neutron activation of stable isotopes occurs in the same manner as charged particle activation and produces neutron-rich nuclides that often decay by beta emission. Fission reactions may be regarded as a special type of neutron activation because they are generally induced by neutron capture. Many useful radioactive isotopes are produced in fission reactions, including ^{90}Sr, ^{99}Tc, ^{131}I, ^{133}Xe, ^{137}Cs, and ^{144}Ce. One of the newest medical diagnostic and treatment techniques combines radiochemistry with genetic manipulation. Radioactive nuclides have been attached to monoclonal antibodies created by recombinant DNA techniques to be specific for antigens contained on the surface of cancer cells [54], [55]. The therapeutic agent is thus carried preferentially to the desired site. The technique has proven most effective in treatment of lymphomas and leukemia as opposed to solid tumors.

Great advantage may accrue from using pure or enriched isotopes as target materials in activation processes. The target isotope is often an element that contains several other isotopes as well. Using the natural isotopic mixture may create unwanted radioisotopes in addition to the desired product, and if the desired product is of low natural abundance, the desired product may be only a small fraction of the activated material. For example, iron radioisotopes ^{55}Fe and ^{59}Fe are both useful materials produced by neutron capture from naturally occurring iron isotopes ^{54}Fe and ^{58}Fe, respectively, but have different applications. Because the natural abundance of ^{54}Fe is much greater than that of Fe (5.8 vs. 0.3 %), activation of a normal sample of iron gives nine times as much ^{55}Fe as ^{59}Fe. However, enrichment of the starting material in the target of interest by electromagnetic separation can be performed to alter the final product ratio. By using iron containing 97 % ^{54}Fe, the activation product contains almost exclusively ^{55}Fe. Conversely, if the ^{58}Fe is enriched to 85 %, the product contains less than 5 % ^{55}Fe. Another benefit of preenrichment of target material is the reduction in time and amount of radiation, i.e., energy, needed to produce a given yield of the desired product.

3.4. Industrial Uses

Few applications have been found for specific isotopes in industrial settings. Radioactive species have been used in the construction industry for site characterization and the investigation of construction materials and techniques, including the detection of reinforcing rods and flaws in concrete [59]. In general, however, the use of separated or enriched stable isotopes for industrial purposed is limited by availibility and cost. The separative methods employed for commercial sale of isotopes produce milligram and gram quantities of materials, and the repetitive processing required to obtain significant enrichment is energy-intensive and therefore expensive. Nevertheless, potential markets have been identified for large amounts of enriched stable isotopes if they become cheaper.

Enrichment of one of the isotopes of mercury, ^{196}Hg, has been shown to increase the efficiency of fluorescent lighting by up to 5 % [60]. However, no cost effective method of implementing this technology as been developed. Tagging of products with enriched isotopes has been suggested as an intrinsic method of identifying their origin and to thwart counterfeiting [61]. A subtle change in the isotopic composition of one or more of the constituent materials would serve to unequivocally identify a component made with such material. This method of labeling would be consistent throughout the entire component and could not be obliterated short of destroying the part. Isotopically altered inks have been proposed for use in legal documents, securities, and other printed matter, even paper currency. These incorporate an element such as chromium in altered abundance that could easily be determined by isotope-ratio mass spectrometry to allow detection of forgeries. Isotopic enrichment of silicon has been postulated as a means for increasing the efficiency of integrated circuits. ^{28}Si has greater thermal dissipation efficiency than natural silicon and may allow finer circuitry to be produced on existing equipment. Zinc is used as a corrosion-resistant additive in water-circulation systems of nuclear power plants. Exposed to high neutron fluxes, it eventually becomes a radioactive waste material. Depletion of ^{64}Zn from the natural occurring material results in much lower radioactivity and a significantly shorter half-life in the waste material.

The priority pollutants listed by the U.S. EPA are now commercially available in isotopically altered form. These labeled materials can be added to ordinary (unaltered) materials to allow them to be traced and identify their origin.

4. Isotope Separation [15], [61]

4.1. The Separation Factor

Certain differences in physical and chemical properties of isotopes (see Chap. 2) can be used as a basis for their separation. The behavior of atoms and molecules in a gravitational field, or of ions in an electric or magnetic field, depends directly on the mass and varies individually for isotopes. Statistical differences arising from variations in mass are found for the mean velocity of atoms and molecules at a given temperature, the vapor pressure, and the diffusivity. Indirect dependence is found for properties related to vibrational frequencies and the zero-point energy of atoms and molecules; melting and boiling points, as well as equilibrium and kinetic isotope effects, fall into this category.

For any given method of isotope separation, the amount of enrichment that can be expected is given by the *elementary separation factor* q_0. This quantity is specific to the process employed and the conditions under which separation is performed. Derivation of the separation factor may be generalized by considering a material containing an isotope of interest with a mole fraction N (i.e., the number of moles of the target isotope divided by the total number of moles present). After a short time, any enrichment process operating on a quantity B of material will result in a portion of that material δB which is enriched in the target isotope, and a portion $B-\delta B$ which is depleted in that same isotope. The mole fraction of the target isotope in the enriched portion is defined by N' and the mole fraction in the depleted fraction by N''. For a binary mixture, the elementary separation factor is then defined by the equation

$$q_0 = \frac{N'/(1-N')}{N''/(1-N'')} = \frac{R'}{R''} \tag{14}$$

where R is the relative abundance of the isotope, R' the abundance in the enriched portion, and

R'' the abundance in the depleted portion. For an enrichment process that occurs under conditions of thermodynamic and kinetic equilibrium, the separation factor is always equal to the elementary separation factor even after the process has been halted. For a process exhibiting a kinetic isotope effect, the equality holds only while the process continues. The system comes to equilibrium after the process has been halted, and the separation factor may be determined by the amount of material that has undergone the particular transfer or transformation involved.

In most cases, the elementary separation factor is small, typically close to 1.0. If a process is allowed to operate on a quantity of material, the enriched fraction will have only a slightly higher concentration of the target isotope than the depleted fraction. To achieve a large increase in concentration, the elementary separation effect must be multiplied by subjecting the enriched fraction to another separation and repeating this sequence until the concentration of the target isotope reaches the desired level. Multiplication of the elementary separation effect may be accomplished in one of two ways: by a discontinuous process acting on a single batch of material or by a continuous process involving many interconnected steps.

4.1.1. Continuous Processes and Cascades

In a continuous process, material is introduced into and removed from various parts of the enrichment operation at constant rates. A continuous process usually employs many individual separation units, called *elements,* usually identical and capable of enriching the target isotope to an extent determined by the elementary separation factor. To handle large quantities of material, many individual elements may be connected in parallel to form a *stage.* To multiply the elementary separation effect, stages are arranged in series to form a *cascade.* In a cascade, the enriched output from one stage, called the *product* or *heads,* is used as feed for the next stage. The process acts on this material, with an initially higher target isotope concentration, to enrich the desired isotope again by the elementary separation factor. Because the product from a stage contains only part of the feed, each stage in a cascade has fewer elements than the preceding stages.

The depleted material removed from each stage, called the *tails,* can be discarded or recycled, depending on the economics of the process and the substances involved. Recycling involves adding the tails from one stage to the feed of a stage upstream in the cascade (i.e., a point of lower enrichment), creating a *countercurrent cascade.* Recycling the tail to the stage immediately upstream creates a symmetrical cascade, whereas recycling two or more stages upstream is said to be asymmetrical. Another method used to maximize the quantity of enriched product from a given amount of initial feed material is to process the tails of the first stage of the cascade. This fraction is of lower concentration than the initial feed and is generally of no use for enrichment. However, it does contain some of the target isotope and thus may be used as feed for a series of stages operating at lower concentrations, in a *stripping section,* to yield a product at concentrations useful in the enrichment section of the cascade. The utility and design of a stripping section is determined by the cost of the feed material compared to the cost of the total enrichment process. Figure 8 illustrates a simple symmetrical countercurrent cascade with a stripping section.

Figure 8. Symmetrical countercurrent cascade

The enrichment that occurs in an element of the cascade depends on several factors. The cascade has a feed with flow rate L, with a mole fraction of target isotope N and output in two forms: an enriched product with flow rate L' at mole fraction N', and a depleted tail with flow rate L'' at mole fraction N''. The portion of the feed that is removed as product is called the *cut* θ, and it determines the flow rates of the product and tails streams:

$$L' = \theta L$$
$$L'' = (1-\theta)\, L \tag{15}$$

Conservation of matter requires that

$$L = L' + L''$$
$$LN = L'N' + L''N'' \tag{16}$$

Several equations define the terms needed to establish relationships among the various streams and their isotopic concentrations. The ratio of relative abundance in the product and tail streams is called the *separation factor q,* which, if no remixing of the streams occurs, is given by (cf. Eq. 17):

$$q = \frac{N'/(1-N')}{N''/(1-N'')} = \frac{R'}{R''} \tag{17}$$

The *separation gain g* is defined as

$$g = q - 1 = (R'/R'') - 1 \tag{18}$$

The *enrichment factor* α is the ratio of relative abundances of the target isotope in the product and feed streams:

$$\alpha = \frac{N'/(1-N')}{N/(1-N)} = \frac{R'}{R} \tag{19}$$

The *enrichment gain* ε is defined as

$$\varepsilon = \alpha - 1 = (R'/R) - 1 \tag{20}$$

The separation factor and separation gain give a measure of how the process partitions the target isotope between the product and the tails streams, whereas the enrichment factor and enrichment gain measure to what extent the process increases the concentration of the target isotope in the product relative to the feed. Note that all of these equations include the concentration of the target isotope. At low concentrations, this becomes insignificant and the following approximations may be made

$$q = N'/N''$$
$$\alpha = N'/N \tag{21}$$

Applying this simplification and performing a series of substitutions allows the enrichment factor to be expressed in terms of the separation factor and cut:

$$\alpha = \frac{q}{1+\theta\,(q-1)} \tag{22}$$

Figure 9 shows the dependence of the enrichment factor on cut for different values of separation factor. For very large cuts, the enrichment factor tends toward unity; for small cuts, the enrichment factor approaches the separation factor. The cut may thus be optimized to provide the desired combination of quantity of product and degree of enrichment from an individual unit. Because a stage consists of more than one element, the same mathematical treatment applies but with the flow rates multiplied by the number of elements.

Figure 9. Enrichment factor α as a function of cut θ
—· $q = 10$; – – – $q = 5$; – · – $q = 2.5$

In a cascade, a number of stages are connected in series, and in a situation analogous to the individual separation unit, a cascade has feed with a flow rate F and mole fraction N_F of the target isotope, and outputs in the form of product with flow rate P and mole fraction N_P, and tails with flow rate W and mole fraction N_W. These flow rates and concentrations are the external parameters of the cascade; any four external parameters may be used to define the system. Usually, the product flow rate and the concentrations of feed, product, and waste streams are set, which determines the other two flow rates. In a symmetrical countercurrent cascade, the flow rates and concentrations between stages, called the *internal parameters,* are more

complex because the feed for any one stage is a mixture of the product from the stage immediately upstream and the tails of the stage immediately downstream. Other internal parameters are the number of stages and the cut for each stage. All of the internal flow rates can be described as functions of the product flow rate and the cuts of individual stages. The concentration gradient along the cascade is a function of the separation gain and external concentration parameters, and approaches a maximum value given by

$$\frac{\mathrm{d}N}{\mathrm{d}s}=gN\,(1-N) \tag{23}$$

where s represents a given stage.

The separative performance of a single stage, and of a cascade as a whole, is greatest when the product flow rate is zero. This is essentially a steady-state situation in which no new feed is introduced and all the effort of the process goes into achieving the maximum concentration gradient. If enriched material is to be removed from the cascade, a net transport f_1 of material through the cascade must occur, which results in a decrease in the concentration gradient. The net transport is at a maximum $f_{\max}$ when the product flow rate is equal to the feed flow rate. In this case, there is no tails flow and the concentration gradient is zero; i.e., no separation of isotopes occurs. This also implies that the value of $f_{\max}$ with respect to the tails flow rate must be the same as the maximum value of the concentration gradient multiplied by the tails flow rate L''; i.e.,

$$f_{\max}=gN\,(1-n)\,L'' \tag{24}$$

Thus, the net transport and concentration must be optimized to give an efficient yield of enriched product from the cascade. The *separative work E* of a stage, which is the product of the concentration gradient and the net transport with respect to the tails flow rate, is defined as

$$E=\frac{\mathrm{d}N}{\mathrm{d}s}\cdot fL''=\left(N'-N\right)\left(N-N''\right)L'' \tag{25}$$

The most efficient operation of a stage occurs when the value of E is maximized. This is true when the net transport and the concentration are both one-half of their maximum values:

$$E_{\max}=1/4g^2N^2\,(1-\mathrm{N})^2\,L'' \tag{26}$$

The separative work of a stage is therefore concentration dependent. However, the *separative power* δU, obtained by dividing the separative work by the concentration terms, is an intrinsic property of a stage. Its maximum value $\delta U_{\max}$ is given by

$$\delta U_{\max}=\frac{E}{N^2\,(1-N)^2}=\frac{1}{4}g^2L'' \tag{27}$$

Two important special cases of cascades can be considered. In the *ideal countercurrent cascade,* streams (product and tails) that mix to form the feed of a given stage have the same isotopic abundance. For an ideal cascade, the relationship between enrichment factor and separation factor is

$$\alpha=\sqrt{q} \tag{28}$$

For any stage s, the cut is a function of the enrichment factor and the isotopic abundance of the target isotope in the feed:

$$\theta=\frac{1+\alpha R_{\mathrm{s}}}{(1+\alpha)\,(1+R_{\mathrm{s}})} \tag{29}$$

The number of stages S needed to permit a cascade to operate ideally is a function of the relative isotopic abundance of the initial feed R_0, the desired product abundance R_{p}, and the enrichment factor:

$$S+1=\frac{\ln\,(R_{\mathrm{p}}/R_0)}{\ln\alpha} \tag{30}$$

When the abundances in the feed and product are low, the relative abundances may be replaced by the mole fractions (N_0 and N_{p}) without significantly altering the results of the calculations.

Given a small value for the enrichment factor, typical for most separation processes, the number of stages required to establish an ideal cascade can be very large. For example, if enrichment of ^{235}U from its natural abundance of 0.71 % to 3.0 % is desired and a process is employed with a separation factor of 1.004 (typical for gaseous diffusion), the number of stages required in an ideal cascade for this enrichment is more than 2100.

The concentration gradient in each stage of an ideal cascade is given by

$$\frac{dN}{\mathrm{d}s}=\varepsilon N\,(1-N)=\frac{1}{2}gN\,(1-N) \tag{31}$$

This is the concentration gradient for optimum separative work (see Eq. 32), and by setting the net transport to its optimum value, one can see that an ideal cascade is the most efficient design for isotope separation. The separative power of this type of cascade is simply the separative power of the individual stages multiplied by the number of stages n; i.e.,

$$\Delta U = \delta U_{\max} n \tag{32}$$

The second case is that of the *square cascade* in which the flow rates of the feed streams of all stages are maintained at a constant value (the exception is the last stage because no recycling of a tails stream occurs at this point). This implies that the product and tails streams that mix to form the feed stream for a given stage usually have different isotopic abundances. The enrichment factor thus varies from stage to stage. The cut for stages in a square cascade can be arranged in two ways, either a constant value of θ for all stages or an arrangement in which the value is the same for alternate stages (i.e., all odd-numbered stages have one value θ_1, and all even-numbered stages have another value θ_2). In both cases the values are constrained by the equation

$$\theta_1 + \theta_2 = 1 + (P/F) \tag{33}$$

where P and F are the flow rates of the product and feed, respectively.

The constant cut situation ($\theta_1 = \theta_2$) is more common and is used in square cascades for the enrichment of various isotopes by distillation, thermal diffusion, and centrifugation. The maximum concentration gradient for a square cascade is given by

$$\frac{\mathrm{d}N}{\mathrm{d}s} = gN(1-N) - \frac{2P}{L}(N_{\mathrm{p}} - N) \tag{34}$$

and therefore, a lower value results for the separative power than for the ideal cascade when the net transport for the square cascade is optimized. In general, square cascades are less efficient than ideal cascades because some of the separative work done in each stage is lost when the product stream is mixed with a less highly enriched tails stream to form the feed for another stage. Despite this loss of separative work, square cascades are often preferred to ideal cascades as the throughput can be significantly greater and because capital costs are often lower. The total separative power of a square cascade is optimized around a mean value for the separative power of the individual stages; i.e.,

$$\Delta U = \delta U_{\mathrm{avg}} n \tag{35}$$

4.1.2. Discontinuous Processes

In a discontinuous process, a quantity of material is subjected to an enrichment process which increases the concentration of the desired isotope in the form or phase that remains in the apparatus and removes part of the depleted form or phase. The process is halted after a period of time, and the enriched material is removed. Material may be added to the apparatus continuously during the enrichment process, but the term discontinuous is applied because the process must be halted to recover the product. An example is *Rayleigh distillation,* which is used to enrich deuterium in the form of heavy water.

A rigorous mathematical treatment is not given here, but in principle, vapor above the liquid in the distillation apparatus is in equilibrium with the liquid and has a higher concentration of the more volatile species. The process begins with material having a relative abundance R and quantity Q of the more volatile isotope. The relative abundance of the isotope in the vapor phase is R', with quantity Q'; the abundance in the liquid phase R'', with quantity Q''. The separation factor is then given as in Equation (17) and the enrichment factor as in Equation (19). If a portion of the vapor is continuously removed, the concentration of the less volatile species in the liquid phase increases as material relatively rich in the more volatile species vaporizes to maintain the equilibrium. The separative power of an element employing such a discontinuous process is determined ideally by the separation gain and the cut:

$$\delta U = \frac{G}{2} g_0^2 \frac{1-\theta}{\theta} [\ln(1-\theta)]^2 \tag{36}$$

where G is the feed flow rate in moles per unit time. (The separative power per batch is simply U/G.) For Rayleigh distillation, the cut is optimized at ca. 0.8, which implies that much material is required to achieve a significant enrichment of deuterium.

This enrichment process is complicated by the presence of the target isotope in more than one form. At low concentration, deuterium exists predominantly as HDO, but as the concentration increases, D_2O dominates. Additional complexity is introduced by the fact that the volatility difference between H_2O and the deuterium-containing species decreases with increasing temperature; above ca. 230 °C, the volatility of D_2O is actually greater than that of H_2O.

4.2. Separation Processes

4.2.1. Distillation

Fractional Distillation. Distillation is one of the oldest methods of isotope separation. ASTON used this method unsuccessfully in 1919 in an attempt to isolate the isotopes of neon. UREY and others used distillation to isolate the first enriched fraction of deuterium from liquid hydrogen in 1932.

Distillation is a mass-dependent process because the difference in mass between isotopes results in differences in the reduced mass of molecules containing isotopes of an element. This, in turn, results in higher vibrational frequency for the lighter species, higher zero-point energy, and lower heat of vaporization. The last property is reflected in higher volatility of the lighter species at low temperature (e.g., <100 K). A simplified treatment, which assumes the molecules to be simple harmonic oscillators, gives the average energy of a molecular species as

$$E_{\mathrm{avg}} = \frac{1}{2}h\nu + \frac{h\nu}{e^{h\nu/kT} - 1} \tag{37}$$

As temperature increases, the second term of the expression dominates and tends to equalize the energies of the molecules. Because volatility is a measure of the number of molecules that have energy in excess of the heat of vaporization, this quantity also tends to be equalized at high temperature. Volatility is also affected by the electromagnetic interaction between molecules; this may change the relative volatilities of isotopically substituted species (e.g., $^{11}BF_3$ is always more volatile than $^{10}BF_3$ for this reason). Dipole – dipole interactions may also be important for some isotopically substituted species.

Table 7. Vapor pressure ratios for some isotopic systems

System	Temperature, °C	v_1/v_2
$^3He/^4He$	−271.0	7.0
H_2/HD	−259.4	3.61
	−252.9	1.73
H_2O/HDO	40.0	1.059
	100.0	1.026

For a pure substance, the volatility v is equal to the vapor pressure p. In an ideal mixture, the volatility of any one component is independent of other components and is defined as the ratio of the partial pressure p_{p} of the component in the vapor phase to the mole fraction of the component in the liquid phase N. The partial pressure is also given by the mole fraction n in the vapor phase multiplied by the total pressure p_{T}; therefore,

$$v = p_{\mathrm{p}}/N = P_{\mathrm{T}}\,(n/N) \tag{38}$$

A two-component system has two such equations:

$$\begin{aligned} v_1 &= p_{\mathrm{T}}\,(n_1/N_1) \\ v_2 &= p_{\mathrm{T}}\,(n_2/N_2) \end{aligned} \tag{39}$$

and the ratio of the two volatilities can be written as

$$v_1/v_2 = \frac{n_1/n_2}{N_1/N_2} \tag{40}$$

The numerator of this equation is the ratio of relative abundance of the components in the vapor phase, and the denominator is the ratio of abundance in the liquid phase. If the components are isotopes or isotopically substituted species, the ratio of volatilities is, according to the definition in Equation (17), the elementary separation factor, i.e.,

$$q_0 = v_1/v_2 \tag{41}$$

Most systems, however, are not ideal, and the volatility of individual components varies with composition, voltaility being proportional to the vapor pressure of the pure substance. Equation (41) remains valid, but the values of v_1 and v_2 must be determined experimentally to find the actual elementary separation factor. Table 7 lists vapor pressure ratios for a number of isotopically substituted systems at various temperatures.

A simple distillation column, with single boiler and condenser, uses gravity to establish a flow between the vapor rising in the column from the boiler at the bottom and the liquid falling from the condenser at the top. The more volatile species concentrates in the vapor phase and the less volatile in the liquid phase. Such an apparatus enriches an isotopic mixture only to the extent allowed by the elementary separation factor. To multiply the effect, many simple columns can be arranged in parallel and series to form a cascade. A more efficient method involves fractionating columns in which intimate contact occurs between liquid and vapor phases at many points throughout the column and continual exchange of isotopic species between phases can occur. Figure 10 shows one arrangement of a fractionating column, called a *bubble-cap plate* column. Vapor traveling upward from the boiler passes through the caps and bubbles through the liquid lying on top of each plate. When it reaches the top of the column, the vapor condenses and is added to the liquid on the top plate. Liquid overflowing from one plate passes down the column to the plate immediately below. The top plate has the highest concentration of the more volatile species in both the liquid and the vapor phases, whereas the bottom plate has the highest concentration of the less volatile species, with a concentration gradient established along the column. Thus, the fractionation column can be envisoned as a cascade, with each plate being a stage. Ideally, an equilibrium is established between the vapor and liquid phases at each plate, with the vapor enriched in the more volatile component to the extent allowed by the elementary separation factor. Such an equilibrium situation leads to the concept of *theoretical plates*. In practice, with a continual flow of feed material into the boiler at the bottom of the column and enriched product removal at the top, only a fraction (but usually a large fraction) of the elementary separation factor is realized for each plate.

Figure 10. Bubble-cap column

Another arrangement of the fractionation column uses a packing material (beads, rings, or other material with a large surface area). Liquid condenses on the packing material and flows downward, in intimate contact with the vapor traveling upward at all times. This situation is equivalent to a cascade with continuous stages. A stage may be envisioned as the length of packed column over which the vapor attains the same concentration of the more volatile species as it would above one theoretical plate in a bubble-cap column. This length is known as the height equivalent of a theoretical plate (HETP).

Distillation was used for large-scale enrichment of heavy water in the Manhattan Project during World War II [62]. Large quantities of highly enriched D_2O were needed as a modera-

tor for nuclear reactors. Between January 1943 and October 1945, three plants were built and operated by Du Pont in the United States (Morgantown, West Virginia; Childersburg, Alabama; and Newport, Indiana) which produced more than 1 t of D_2O per month when operating at full capacity and a total of 20.7 t of D_2O during their overall operation. The distillation process enriched heavy water from a natural abundance of 0.0143 % (D_2O equivalent, actually present, almost exclusively, as HDO in normal water) to 88 – 92 % D_2O. This material was subjected to further enrichment to 99.8 % by electrolysis (see Section 4.2.8).

The distillation cascade at the Morgantown facility, the smallest of the three, consisted of eight stages: half of the columns in the first stage were comprised of *tunnel-cap plates* (similar to bubble-cap plates), whereas the remainder of the first stage and the second and third stages had bubble-cap plates. The last five stages were packed columns. The first stage contained five pairs of large columns in series, ca. 4.6 and 3.6 m in diameter and ca. 30 m tall, with 79 and 89 plates, respectively, in each column. The second stage was made up of a pair of slightly smaller columns with 71 and 82 plates; the third stage consisted of a single column, 1 m in diameter, with 71 plates. The remaining columns were packed with Raschig rings to a height of 22 m. The final column had an HETP of ca. 0.5 m (and thus had ca. 45 theoretical plates). Figure 11 shows a schematic of the distillation unit. The first-stage columns were operated at low pressure to take advantage of the greater difference in volatility between H_2O and HDO (or D_2O) at lower temperature. The large holdup capacity of the system (amount of water contained in the system at any given time) meant that it was slow to react to changes in process parameters and three months was usually required for a change in equilibrium.

The efficiency of distillation was low; ca. 2.8 % of the quantity of D_2O present in the feed material was actually recovered at the Morgantown facility, the most efficient of the three plants. This meant that for every 10^3 t of normal water processed, 4.2 kg of enriched heavy water was obtained. The 20.7 t of material from the three distillation facilities was produced at an average cost of \$ 0.46 per gram.

Distillation of liquid hydrogen was also examined by scientists and engineers connected with the Manhattan Project [62, p. 82]. This process was abandoned at the developmental stage in favor of water distillation because of the mature state of technology available for the latter process, and the lack of experience in operating equipment and handling large quantities of materials at temperature close to absolute zero. The efficiency of hydrogen distillation for the separation of deuterium is much greater than that of water distillation. Table 7 shows that at the respective triple points, the ratio of vapor pressure for H_2/HD is three times as great as the ratio for H_2O/D_2O (the difference is six times when the H_2O/HDO ratio is considered). The process is used on a laboratory or pilot-plant scale to enrich small quantities of deuterium.

The isotope ^{18}O is also obtained by distillation of water. This process is complicated because deuterium separation also occurs during water distillation and has a larger enrichment factor. To improve efficiency, water that has been depleted in deuterium is used as the feed for oxygen isotope separation, so the waste product from heavy-water enrichment is a good feedstock.

Another isotopic system examined was boron, in which ^{10}B and ^{11}B can be separated by distillation of BF_3 [63]. This separation is aided by the fact that fluorine is mononuclidic. The vapor pressure ratio of $^{10}BF_3$ to $^{11}BF_3$ is less than 1.0 at all temperatures; i.e., the heavier isotopic species is more volatile. Because ^{10}B, with 19.8 % natural abundance, is usually the desired species, this system lends itself to distillation by a discontinuous, batch process. In 1945, again in connection with the Manhattan Project, a large quantity (50 kg) of boron, enriched in the ^{10}B to more 90 %, was produced by distillation. The process used the dimethyl ether complex of boron trifluoride, $(CH_3)_2O \cdot BF_3$, to avoid the lower temperature needed if pure boron trifluoride is used. During the developmental phase of the project the vapor pressure ratio of the isotopically labeled complexes was found to be very close to 1.0 (again, the higher mass compound was the more volatile) and could not, in itself, account for the magnitude of the experimentally determined separation factor. Further experiments showed that an exchange reaction involving free $^{11}BF_3$ and the $(CH_3)_2O \cdot {}^{10}BF_3$

Figure 11. Heavy-water distillation unit at Morgantown

complex in the vapor phase exhibits an equilibrium isotope effect (see Section 2.2.2) that is responsible for the major portion of the separation of boron isotopes.

Helium isotopes have the highest ratio of vapor pressures listed in Table 7 and could be separated very efficiently by distillation. Problems arise because of the need to work at very low temperature. Isotopes of chlorine can be separated by distillation of carbon tetrachloride. Interestingly, the most volatile species in the isotopic mixture contains the light isotope of chlorine, ^{35}Cl, and the heavy isotope of carbon, ^{13}C.

Molecular Distillation. Under ordinary distillation conditions, an equilibrium is established between the vapor and liquid phases at each plate or on the surface of the packing material in a fractionation column. This is a dynamic situation in which atoms or molecules are continually exchanged between phases by evaporation and condensation, with the rates of these two phenomena being equal at equilibrium. Increased efficiency of distillation results if a nonequilibrium situation can be maintained in which the species evaporating from the liquid are removed from the system immediately by condensation on a nearby surface; this process is called *molecular distillation.* In this case, the composition of the material evaporating from the liquid is determined only by the relative evaporation rates of the components of the liquid phase. Langmuir's hypothesis states that at low temperature and, therefore, low pressure, the evaporation rate is independent of any material already present in the vapor phase. Thus, the evaporation rate is equal to the condensation rate under equilibrium conditions. The condensation rate is determined by assuming the vapor to be an ideal gas that follows the kinetic theory of gases. From this theory, the number of molecules (or atoms) and their velocity may be found, which leads to

$$R_{\mathrm{evap}} = \frac{p}{(2\pi MRT)^{1/2}} \tag{42}$$

where R_{evap} is the evaporation rate, p the partial pressure, M the molecular (or atomic) mass of the species, R the gas constant, and T the absolute temperature. Langmuir used this equation to determine the vapor pressure of pure metals at various temperatures. For isotope separation in a situation analogous to that developed for ordinary distillation in Equations (28) – (30), the elementary separation factor for a two-component system under ideal conditions of molecular distillation is given by

$$q_0 = \frac{R_{\mathrm{evap}_1}}{R_{\mathrm{evap}_2}} = \frac{V_1}{V_2} \cdot \frac{M_1^{1/2}}{M_2^{1/2}} \tag{43}$$

Thus, molecular distillation has a separation factor that is larger by a factor of the square root of the mass ratio than ordinary distillation under equilibrium conditions. The method has been

used successfully to separate isotopes of mercury on a laboratory scale [64] and as a means for separating lithium isotopes [65].

Some problems arise with the molecular distillation process that can severely limit its effectiveness. The elementary separation factor may be reduced from the ideal value if removal of the evaporating material is not quantitative. Atoms or molecules can return to the liquid phase after initial evaporation because of collisions with other atoms or molecules before condensing on the receiving surface or because of reevaporation from the receiving surface. These phenomena may change the ratio of evaporation rates or at least reduce the flow rate of the process. In addition, because boiling of the liquid phase does not occur, mixing of that phase to maintain a homogeneous distribution of components does not occur readily. The surface layer of the liquid becomes depleted in the most volatile species by evaporation more rapidly than diffusion through the liquid can replenish that component. In effect, the mole fraction of the most volatile species in the feed becomes lower than that of the original mixture and the enrichment gain suffers as a result. Apparatus and process conditions that allow mixing of the liquid and maximize removal of evaporated material are available. The best operating conditions for molecular distillation are very low pressure and relatively low temperature, but optimum combinations of these conditions usually restrict the number of isotopic systems that can be enriched by this process.

4.2.2. Diffusion

Gaseous Diffusion. The kinetic theory of gases also describes the process of isotope separation by diffusion through a porous barrier or membrane, which is called gaseous diffusion. If a mixture of gases in a container is at thermal equilibrium, the root mean square velocity of any of the species is

$$v_{\mathrm{rms}} = (3RT/M)^{1/2} \tag{44}$$

This indicates that the lighter molecules or atoms have a higher velocity. The number of collisions c, per unit area, with the walls of the container is given by

$$c = n' \, (RT/2\pi M)^{1/2} \tag{45}$$

where n' is the number density of the species in the container. If one wall is perforated with small holes and the pressure on the other side of the wall is such that essentially no molecules or atoms return to the original container, Equation (45) also gives the rate of *molecular effusion* w through the openings in the wall. (The term effusion is used when the mean free path of the molecules is greater than the diameter of the pores in the barrier). If the ideal gas law is used to substitute pressure for the number density, the rate of effusion is given by

$$w = p/\,(2\pi RT/M)^{1/2} \tag{46}$$

and is the basis for the *Knudsen cell,* which is used to determine vapor pressures. Note that this equation is the same as that derived for molecular distillation (Eq. 42). In a mixture of gases, the partial pressure of any component is given by the total pressure multiplied by the mole fraction of that component. For a two-component mixture, the mole fraction can be expressed as N'', and $1 - N''$, where N'' is the mole fraction of the lighter species. A ratio of the effusion rates for the two components gives

$$\frac{w_1}{w_2} = \frac{N''p}{(1-N'')\,p} \cdot \frac{(2\pi RTM_2)^{1/2}}{(2\pi RTM_1)^{1/2}} \tag{47}$$

If the difference $1 - N''$ is close to the original mole fraction in the container (i.e., N), the elementary separation factor for a gaseous diffusion process is simply the square root of the ratio of masses of the two species:

$$q_0 = (M_2/M_1)^{1/2} \tag{48}$$

which may be approximated by

$$q_0 \simeq 1 + \frac{M_2 - M_1}{M_2 + M_1} \tag{49}$$

In fact, the separation factor is only proportional to the mass ratio because of non-idealities in the process. The size of the openings and the mean free path of the molecules or atoms involved lower the separation efficiency. Although the efficiency increases as the size of the openings decreases and the mean free path increases, these quantities are restricted by the physical parameters of the barrier and of the effusing material. Also, the pressures that exist in large-scale

diffusion systems cause reductions in the concentration gradient across the membrane in two ways. A significant back pressure, on the side of the barrier receiving the gas mixture enriched in the lighter species, results in diffusion in the opposite direction. An increase in the pressure on the side of the barrier containing the feed causes viscous flow through the membrane that does not result in isotope separation. A particular membrane has a separation efficiency that depends on operating pressure and temperature and on properties (e.g., viscosity) of the gas. Surface effects lower the separation efficiency by reducing the mean free path of particles colliding with the container walls.

Gaseous diffusion has been used successfully for several isotopic systems. The largest application of the diffusion process is for the enrichment of the fissile isotope of uranium (^{235}U) for nuclear power plants, nuclear propulsion units for submarines and surface ships, and nuclear weapons. The compound used for gaseous diffusion is uranium hexafluoride (UF_6) which has several distinct advantages. It sublimes at 56.5 °C (101.3 MPa), has a relatively low viscosity (1.76 mPa · s at 101.3 kPa and 20 °C), and contains only the mononuclidic element fluorine in addition to uranium. Drawbacks to this compound are its small mean free path and its reactivity; uranium hexafluoride is a good fluorinating agent, which reacts with most organic compounds, with water, and with many metals. Construction materials must be selected with this chemistry in mind. Experimental diffusion apparatuses include fluorinated hydrocarbons and metals such as silver and aluminum, which form a protective fluoride surface layer. Water must be rigorously excluded because its reaction with uranium hexafluoride forms uranyl fluoride (UO_2F_2), a high-melting solid, and hydrofluoric acid, which presents severe corrosion problems.

The first diffusion plant for the separation of uranium isotopes was constructed in Oak Ridge, Tennessee, and became operational in 1945. More cascades were added to the Oak Ridge facility and additional plants were constructed in Paducah, Kentucky, and Portsmouth, Ohio, in the 1950s [14, p. 195]. The Oak Ridge and Portsmouth plants each have about 4000 stages in series, whereas the Paducah plant has two cascades in parallel, both with about 880 stages. The power requirement for operation of the plants at full capacity is 6000 MW, and the total separative work available is ca. 17 000 t SWU (separative work units) per year. At one time, operation of the three plants was coordinated, with the naturally occurring isotopic mixture of uranium processed at the Paducah facility to enrich ^{235}U from 0.0714 to 0.96 %. This material served as the feedstock for the other two plants. The Oak Ridge plant enriched the isotope to ca. 4 %, which could be used as fuel in nuclear power reactors. Some of this material was sent to the Portsmouth facility where it served as additional feed for enrichment to >96 % and was useful for nuclear propulsion reactors in submarines and for nuclear weapons. At present, the demand for enriched uranium is low, and the Oak Ridge plant has been shutdown. The other two facilities operate at reduced capacity. Diffusion plants for the enrichment of uranium are also located in Great Britain, France, Russia, and China.

Mass Diffusion. Mass diffusion also exploits the differences in molecular velocity of isotopically substituted species. This is essentially the process responsible for the isotopic fractionation of nitrogen-containing compounds in natural gas (see Section 2.3), which leads to separation of the lighter, ^{14}N-containing materials by diffusion through large quantities of methane. The mass diffusion technique allows a mixture of isotopically substituted compounds to diffuse through a third gaseous material, called the separating agent, as the agent flows through a porous barrier or screen [66]. *Sweep diffusion* is based on the same physical phenomenon but does not employ a barrier, it is the process actually involved in the natural enrichment of nitrogen compounds [67]. Both methods are based on the fact that a lighter species has a higher diffusion coefficient through the separating agent.

For example, if a container is partitioned into two areas by a porous screen and one side initially contains the isotopic mixture and the other side the separating agent, diffusion through the screen eventually results in an equilibrium in which the concentration of each species is the same in both areas. However, if the gases on the side initially containing the separating agent are examined some time before equilibrium is reached, the ratio of the lighter to heavier iso-

topic species is greater than their initial ratio (i.e., the lighter material is enriched) because the lighter species diffuses through the separating agent faster than the heavier material. The elementary separation factor for this simple process may be approximated by the ratio of the diffusion coefficients:

$$q_0 = D_1/D_2 \tag{50}$$

where the subscripts 1 and 2 represent the lighter and heavier species, respectively.

Certain properties must be considered when selecting a separating agent: selectivity of the agent for the species to be separated (also known as separability of the materials in the agent), high diffusion coefficients of the isotopic species in the agent, and easy separation of enriched material from the separating agent. No chemical interaction should occur between the separating agent and the isotopic species. The first two factors work at odds with each another. The selectivity of the separating agent increases with increasing molecular weight, but the diffusion coefficient decreases at the same time. Generally, a separating agent with a molecular weight close to that of the materials used for enrichment gives the best combination of properties.

Separation of the isotopic components from the agent is simplified by selecting an agent with a boiling point much higher than those of the isotopic materials. This aids in removing and recycling the separating agent by condensation from the agent – product mixture. When the molecular masses of the materials are very similar, the elementary separation factor may be approximated by

$$q_0 \simeq 1 + \frac{M_2 - M_1}{M_2 + M_1} \cdot \frac{M_0}{M_0 + (M_1 + M_2)/2} \tag{51}$$

where M_1 and M_2 are the masses of the lighter and heavier isotopically substituted species, respectively, and M_0 is the mass of the separating agent. This equation resembles that given for gaseous diffusion (Eq. 49) but includes a second mass factor contributed by the separating agent that is always less than 1.0. As a result the separation factor for mass diffusion is lower than that for gaseous diffusion for any given isotopic system. The advantage of the process is that it is less technically demanding and is amenable to multiplication of the elementary separation factor by establishing countercurrent flows in a mass diffusion apparatus. Unlike gaseous diffusion, which can only be operated on a large scale, this technique can be used on any scale.

A mass diffusion column, developed by Benedict and Boas in the early 1950s, is shown schematically in Figure 12. It comprises three concentric columns surrounded by a jacket containing cooling water.

Figure 12. Mass diffusion column

The central column is perforated so that gases can pass into the next column. This second column contains some of the isotopically substituted mixture of gases to be separated. A porous

screen separates the second column from the third, which contains the remainder of the isotopic mixture. Countercurrent flow is created by causing the gas in the second column to rise toward the top of the apparatus and gas in the third column to flow to the bottom.

The gaseous separating agent, produced by an evaporator at the bottom, rises through the central column, diffuses through the holes into the second column, and then through the screen into the third column, and condenses on the cooled outer wall. The liquid separating agent flows to the bottom of the column and is returned to the evaporator to be recycled. Enrichment of the isotopic mixture is a result of the flow of separating agent from the central column to the outer wall, which carries the isotopic mixture of gases with it and establishes a radial concentration gradient. This induces back diffusion of the isotopic species toward the center. Because the diffusion coefficient of the lighter isotopic compound is greater than that of the heavier one, the former flows back toward the center at a higher rate. Thus, gas flowing upward in the second column is enriched in the lighter isotope and gas flowing downward in the third column is enriched in the heavier isotope. In this kind of diffusion column, separation occurs mainly at the screen where a large isotopic concentration gradient exists between the inner portion of the third column and the outer portion of the second column.

The sweep diffusion apparatus is essentially the same in design, with a central column for introducing the separating agent but no screen dividing the remainder of the apparatus into two columns. The flow of separating agent again creates a concentration gradient along the radius of the column and allows back diffusion of the isotopic mixture. Here, the isotopic gradient is essentially linear across the radius of the outer column, and the elementary separation factor can be calculated theoretically as

$$\ln q_0 = \frac{RT\phi_0}{P}\left[\frac{1}{D_1} - \frac{1}{D_2}\right] r_a \ln \frac{r_a}{r_b} \tag{52}$$

where R is the ideal gas constant, T is the absolute temperature, ϕ is the flow rate of the separating agent, p is the pressure, D_1 and D_2 are the diffusion coefficients of the light and heavy isotopic species, respectively, r_a is the radius of the central column, and r_b is the radius of the outer column. Countercurrent flows are established by differences in the density of the isotopic mixture in different parts of the column. The material is less dense near the center of the column because of the concentration gradient and enrichment of the lighter isotope there, and an upward flow is created. A higher density and a downward flow are created near the outer wall. Countercurrent circulation multiplies the elementary separation effect so that the total separation factor is proportional to the length of the column.

Operation of these types of diffusion column is complicated by several factors. Convection currents within the column may be established which mix gases that have different isotopic ratios, either radially or lengthwise in the column. This reduces the overall separation efficiency because reseparation of these mixtures is required and can be especially troublesome in the sweep diffusion method. The isotopic mixture of gases may be trapped in the separating agent when it condenses on the outer wall of the apparatus, or the isotopic compound may be soluble in the agent. Such trapped and dissolved material is unavailable for enrichment by back diffusion. If heavier isotopic species are trapped at the outer wall (where the concentration is highest) and recycled along with the separating agent, these species can contaminate the lighter fraction near the exit holes of the central column.

Mass diffusion was originally employed for the separation of hydrogen from methane by using steam as the separating agent. Later, the carbon isotopes ^{12}C and ^{13}C were separated in the same way. In 1934, HERTZ developed a mercury vapor diffusion pump to separate the isotopes of neon and achieved a fivefold enrichment of ^{22}Ne. The same type of apparatus has been used to enrich ^{18}O, ^{35}Ar, ^{15}N, and ^{13}C. Researchers in the former Soviet Union have used column-type mass diffusion for separating carbon isotopes, with xylene, water vapor, or $C_2H_2Cl_2$ as the separating agent, and for separating isotopes of neon and argon with water vapor as the agent.

Thermal Diffusion. Thermal diffusion relies on the difference in migration rates of isotopically substituted materials between regions of different temperature. The flow rate of ideal gases is inversely proportional to the square root of the mass at constant temperature (Eq. 42 and 46). If a temperature difference exists, the net

flow of any given component of the gas can be expressed by

$$\phi = \frac{P}{(2\pi RM)^{1/2}} \left[\frac{1}{T_1^{1/2}} - \frac{1}{T_2^{1/2}} \right] \tag{53}$$

where T_1 and T_2 are the lower and higher temperature, respectively, and M is mass of the component. According to this equation, the elementary separation factor for a two-component system should be the square root of the ratio of the masses of the components, the same as that for gaseous diffusion given by Equation (48). This, however, is an oversimplification that does not take into account all of the factors that influence the thermal diffusion of the components.

The complex theoretical treatment of the distribution of molecular velocities in a nonuniform state is not presented here, but it does result in derivation of the elementary separation factor in the following form:

$$\ln q_0 = a \ln (T_2/T_1) \tag{54}$$

where a is the thermal diffusion factor, which is a complex function of the molecular masses, the relative proportions of the components of the mixture, and specific integrals determined by intermolecular interactions of the components. The thermal diffusion factor can be calculated theoretically; for isotopic mixtures, to a first approximation it is

$$a = \frac{105\,(M_2 - M_1)}{108\,(M_2 + M_1)} \tag{55}$$

This value is derived by assuming perfectly elastic spherical particles having no attractive potential. The thermal diffusion factor is then determined experimentally, and a ratio R_T is used to compare the experimental to the theoretical value:

$$a_\mathrm{calc} = a_\mathrm{theo} \cdot R_\mathrm{T} \tag{56}$$

Values for R_T may range from zero to unity. For the $^{12}CH_4/^{13}CH_4$ system, R_T is 0.33; for H_2/D_2, it is 0.5; and for $^{20}Ne/^{22}Ne$, it is 0.65. For most isotopic systems, the separation factor for thermal diffusion is lower than that for either gaseous or mass diffusion. Advantages of this method are its simplicity and the fact that it is applicable to liquid and gaseous systems [68].

A simple thermal diffusion column was developed in 1938. It consisted of a long vertical tube with a conducting wire running along the axis. The tube and reservoirs attached to either end of it hold the mixture to be separated. To establish a temperature gradient across the tube, the outer wall is cooled while the wire is heated electrically. The temperature gradient not only allows elementary separation to take place across the width of the tube, but also causes countercurrent flow along its length. A gas stream enriched in the lighter isotopic species travels upward near the wire, while a stream enriched in the heavier species travels downward near the outer wall. Each stream is continually enriched by exchange, and the multiplication of the elementary separation factor by this process can be several thousand. Early experiments employed a column ca. 2.5 m long and 1 cm in diameter, with a temperature difference between the wire and the wall of ca. 1000 °C. This apparatus achieved threefold enrichment of the concentration of ^{22}Ne. Later devices used interconnected tubes, with a diameter of 8.5 mm and a total length of 13 m, to produce ^{79}Br at 85.5 % abundance by using HBr as the gaseous species [69]. Thermal diffusion is currently used to enrich ^{15}N and noble gases on a production scale.

4.2.3. Gas Centrifugation

The idea of separating isotopes by means of gravitational or centrifugal fields was first proposed by Aston and Lindeman in 1919 in connection with their work on the isotopes of neon. A discontinuous method of centrifugal separation was suggested by Mulliken in 1922. The first successful isotopic enrichment by a continuous process was demonstrated by Beams et al. in 1936 and used to separate isotopes of chlorine. An effort to develop a centrifugation process for the enrichment of ^{235}U as a replacement for the gaseous diffusion processes has been abandoned [70].

To calculate the elementary separation factor for the centrifugal process, consider an ideal gas of molecular mass M and density d [$d = (MP)/(RT)$, where P is pressure] contained in a cylinder (rotor) rotating at an angular veloc-

ity ω. A very thin annulus of gas at a radius r_1 in the rotor has a pressure p given by

$$p = p_0 \exp \frac{M\omega^2 r_1^2}{2RT} \tag{57}$$

where p_0 is the pressure at the axis of the rotor, R is the ideal gas constant, and T is the absolute temperature. The pressure at this annulus is developed by the centrifugal potential $1/2\,\omega^2\,r^2$. Because the effect is dependent on molecular mass, in a mixture of two compounds each would have a partial pressure given by Equation (57). The ratio of partial pressures defines the elementary separation factor for the process:

$$q_0 = \exp \frac{(M_2 - M_1)\,\omega^2 r^2}{2RT} \tag{58}$$

If separation takes place across the entire width of the cylinder, r is the radius of the rotor. Often, however, the effect takes place in a narrow annulus of gas near the wall of the rotor. The value of r then is the difference between the radii defining the inside and outside edges of the annulus, i.e., $r_2 - r_1$. Note also that separation depends on the absolute difference between the masses of the components and not the relative mass difference. When all other factors are constant, the separation factor is the same for a mixture of heavy isotopes as for a mixture of light isotopes having the same mass difference. The separation factor can be increased significantly by increasing the peripheral speed of the rotor and by lowering the temperature. As temperature increases, the average molecular velocity of the gas increases, diminishing the concentration gradient established by the centrifugal force.

Three types of centrifuge are used for isotope separation. The *evaporative centrifuge* consists of a rotor with a hollow shaft along its axis. The apparatus is evacuated, and a liquid isotopic mixture is introduced at the bottom of the rotor. When the rotor is spun, the liquid is dispersed in a thin layer over the outer wall. Heat is then applied to evaporate the liquid. Vapor diffuses toward the center of the rotor and is removed through the hollow shaft. Diffusion takes place under the influence of the centrifugal field; thus, material near the axis is enriched in the lighter isotopic species. This technique has been employed successfully to separate isotopes of chlorine by using carbon tetrachloride and isotopes of bromine by using ethyl bromide. Drawbacks of this process include the fact that it is discontinuous; as separation proceeds and the charge is depleted, the concentration of the lighter isotopic species removed at the center of the machine decreases. The efficiency of separation cannot exceed the elementary separation factor and only approaches that value at very slow withdrawal rates at the beginning of the withdrawal process. If only a portion of the liquid is evaporated from the outer wall, enrichment of the heavier species can be multiplied to some extent. This may be thought of as analogous to the batch distillation.

The first continuous separation process was achieved with the *cocurrent centrifuge.* In this apparatus, a gaseous mixture of the isotopic species is introduced at the bottom of the spinning rotor in two concentric streams, one near the wall of the cylinder and one closer to the axis. The streams flow upward and are removed at the top. The centrifugal field causes radial transport of the components of each stream. The heavier isotopic material in each stream is carried further toward the outer wall of the rotor because of its higher molecular mass. Opposing the transport of the components is diffusion toward the center, which is greater for the lighter component. These phenomena result in enrichment of the inner stream in the lighter isotopic species and the outer stream in the heavier species. As with the evaporative technique, enrichment by the cocurrent centrifuge is limited to the elementary separation factor, but methods have been proposed to multiply the effect. One technique divides the interior of the rotor into a series of vertically stacked compartments such that the inner part of one is connected to the outer part of the next higher compartment. This arrangement forces mixing of the inner and outer streams of gas, creating a situation analogous to column fractionation (see Section 4.2.1). Each compartment can be thought of as a plate of the column.

The most successful means of multiplying the elementary separation factor has been achieved with the *countercurrent centrifuge* (Fig. 13). The feed gas mixture is introduced into the rotor along the axis, near the middle, from a hollow central shaft. The product and tails are withdrawn by scoops at the top and bottom of the rotor, respectively. The entire rotor assembly is encased in an evacuated vessel to minimize drag

on the rotating cylinder. The bearings are critical to the apparatus because they must support the rotor and allow it to turn freely, but must damp out any vibrations that would disrupt the dynamic stability of the rapidly spinning rotor.

Figure 13. Countercurrent gas centrifuge
a) Magnetic bearing and damping assembly; b) Rotating baffle; c) Center post (stationary); d) Rotor; e) Casing; f) Electromagnetic motor; g) Bottom bearing; h) Bottom scoop (waste); i) To vacuum system

As with the countercurrent mass diffusion column, the elementary separation effect is multiplied by establishing countercurrent flows along the length of the rotor. A concentration gradient is thus established in the axial direction which, in a rotor with a large ratio of length to radius, is greater than the radial concentration gradient created in either the evaporative or the cocurrent design. Flows are induced in the gas by the action of stationary scoops or by creation of a thermal convection profile by heating one end of the rotor and cooling the other. The ideal flow profile would consist of a very thin layer of gas moving in one direction near the outer wall of the rotor and an equal stream in the other direction spread out over the remainder of the radius of the cylinder. The thermally induced flow profile approximates this situation most closely.

The concentration gradient in a countercurrent centrifuge can be determined by solving a complex partial differential equation with terms that depend on the flow rates and the flow profile. Including the physical properties of the specific isotopic materials and the parameters of the apparatus allows calculation of the theoretical maximum separative power of the countercurrent machine as

$$\delta U_{\max} = (\pi/2)\, D d g^2 Z \tag{59}$$

where D is the diffusion coefficient of the target isotopic species, d is the density, Z is the length of the rotor, and g is given by

$$g = \frac{(M_2 - M_1)\,\omega^2 r^2}{2RT} \tag{60}$$

(the definition of terms is the same as in Eq. 57). Thus, separative power is a function of the length of the rotor, the operating temperature, and most significantly, the fourth power of the peripheral velocity. Separation efficiency is given by the actual value of the separative power under operating conditions. This is proportional to the theoretical value and may be evaluated in four parts:

$$E = \delta U_{\mathrm{act}}/\delta U_{\max} = E_{\mathrm{c}} E_{\mathrm{i}} E_{\mathrm{e}} E_{\mathrm{f}} \tag{61}$$

where E_{c} is the circulation efficiency determined by the internal flow rates, which, consequently, gives the actual concentration gradient in the rotor; E_{i} is the nonideality efficiency, which allows for the fact that product and tail are withdrawn from an operating centrifuge; E_{e} is a factor derived by consideration of the turbulent flow and end effects in the rotor; and E_{f} is the flow efficiency that relates the actual flow profile to the ideal profile. Total efficiency factors of 0.75 and greater have been achieved in experimental situations. A distinct advantage of the countercurrent centrifuge is the large separation factor available from a single machine. This is a consequence of internal recirculation and results in a low throughput for each unit. Therefore, cascades of such machines require many fewer stages than other enrichment techniques (especially gaseous diffusion), and each stage is made

up of a large number of individual units. This allows a degree of flexibility in an enrichment facility because units can be added easily or isolated from each stage to increase or decrease the amount of material processed.

Engineering problems associated with the construction of practical centrifuges include construction materials for the rotor, dimensions of the machine, and the bearing assemblies necessary to support the rotating cylinder. Because the separative effect is affected most significantly by the peripheral velocity, much effort has been concentrated on developing materials and fabrication techniques for centrifuge rotors. The amount of gas in the machine at any time is small, and its mass contributes negligibly to the total mass of the rotating components. Therefore, the stress on the rotor is essentially a result of its own mass, and the maximum peripheral velocity is given by the square root of the ratio of the ultimate tensile strength of the rotor material to its density (i.e., the square root of the specific strength of the material). High-strength steels have good tensile properties, but their high densities lead to lower specific strengths than aluminum and titanium alloys. Composite materials (glass, carbon, or other fibers in a polymer matrix) have the highest specific strengths but are limited by problems in fabricating homogeneous materials that will be stressed equally over the entire rotor in a centrifugal field. Other material considerations include chemical interactions between the construction materials and the gas mixture used for separation. Additional properties of concern include the behavior of the materials for long periods of time under stress, including their fatigue and creep resistance.

The dimensions of the rotor also interact with the properties of the rotor material. When the frequency of rotation coincides with the natural frequency of the rotor material (the *critical frequency*), a resonance is established that results in axial vibration of the rotor. The critical frequencies (simply called *criticals*) are a function of the rotor length-to-diameter ratio and the modulus of elasticity of the rotor material. A machine that operates at speeds below the first critical is known as a *subcritical centrifuge,* whereas one operating above the first or any subsequent higher critical is termed *supercritical.* Operation of supercritical centrifuges involves the added problems of acceleration of the rotor through one or more criticals and maintenance of an operating speed between resonance frequencies.

Most of the work on the gas centrifuge has been directed toward enrichment of uranium isotopes; thus, specific information about equipment and capacities is classified by the governments involved. Experimental machines for this separation have been built and operated in the United States, Great Britain, France, Germany, Russia, the Netherlands, Italy, and Japan. A facility located in the Netherlands and owned by the joint Dutch – English – German consortium URENCO, with a capacity of about 300 t of separative work per year, is currently producing enriched uranium for nuclear power reactors. Another production facility is being operated in Japan. A demonstration plant was constructed at Oak Ridge, Tennessee, with 120 machines that operated for more than two years to provide data on reliability. Three production facilities with over 40 000 centrifuges were originally scheduled to be brought on line in the late 1980s but, because of the decrease in demand for enriched uranium, the program was canceled. Centrifugation has recently been transferred to the private sector for the separation of non-radioactive isotopes.

4.2.4. Nozzle Separation

Nozzle separation was developed in the mid-1950s [71]. The separative effect relies on the difference in diffusion rates and the effect of a centrifugal field on isotopically substituted species in an expanding stream of gas flowing at supersonic speed. The original apparatus employs a tube with a small nozzle from which the gas mixture to be separated flows at high velocity. The stream of gas is permitted to expand into an area adjacent to the nozzle where a pressure gradient in the gas is established transverse to the direction of flow–higher pressure at the center of the stream and lower pressure at its periphery. As described for centrifugal separation, the rate of diffusion of gases in a pressure gradient depends on the mass of the species involved; lighter species diffuse at a faster rate and become enriched in areas of lower pressure. Therefore, gas at the periphery of the expanding jet is enriched in the lighter isotopic species. The gas stream is then divided, and the two components–

one enriched in the heavier species, the other in the lighter species–are collected separately.

The elementary separation factor for the nozzle process is a complex function of several factors, including the masses of the isotopic species, the inlet pressure, and the expansion ratio of the gas. Unlike other enrichment techniques described here, the elementary separation factor in this case is also related directly to the cut taken in the collection portion of the device. Because of these complicated variables, the factor is determined experimentally for any given nozzle and collector configuration and operating conditions.

Figure 14. Nozzle separation apparatus
a) Feed gas, 5 mol% UF_6, 95 mol% He; b) Light fraction enriched in He and ^{236}U; c) Heavy fraction depleted in He and ^{236}U; d) Knife edge; e) Curved wall; f) Nozzle

The apparatus described above has several drawbacks because large pressure differences must be maintained between various parts of the device and the throughput is low. For the enrichment of uranium isotopes, a different design has been devised; it is shown in cross section in Figure 14. In this apparatus, an approximately semicircular groove is cut into a long piece of metal. Two blades extend into the groove to create the nozzle (actually a slit in this arrangement) and the collector. The first blade has a curved side with a smaller radius of curvature than the groove, whereas the second has a knife edge. Gas is forced through the slit formed by the groove and the first blade. Because of different radii of curvature of the two pieces, the gas expands in the space between the blade and the groove. The gas is made to expand at supersonic speed by maintaining a pressure difference across the nozzle. The gas stream follows the curved wall of the groove and is then divided into two components by the knife edge. The gas traveling along paths of smaller radii of curvature is enriched in ^{235}U, whereas that which follows the wall more closely is enriched in ^{238}U.

The separating effect in this nozzle process is mainly a result of the centrifugal forces imposed on the gas stream. Lighter isotopic species are more easily deflected into a curved path and, thus, are preferentially guided into the center section of the collection part of the device by the knife edge. A large proportion of helium is used in the feed gas. Because of its low atomic mass, helium increases the rate of gas flow and the centrifugal force on the uranium compounds. By diluting the feed gas mixture, helium also hinders diffusion and remixing of the isotopic species. Separation gains for this process can be high and usually lie between those of gaseous diffusion centrifugation.

Individual separation units have been combined in stages to form a cascade on a pilot-plant scale in Germany. Although the efficiency of the plant, determined mainly by power consumption, is such that it is not economically competitive with gaseous diffusion, the technique has certain advantages. The proces requires fewer stages to achieve the same degree of enrichment as gaseous diffusion, so the equilibrium time is less (ca. 10 – 100-fold) than that of gaseous diffusion. This means that operating conditions may be changed much more rapidly and varied over a much broader range in this process. Simply by changing the temperature and pressure, the capacity and, therefore, the power consumption can be varied by 50 % or more.

4.2.5. Electromagnetic Separation

Electromagnetic separation is based on the same principles as mass spectroscopy (see Section 1.4) [72]. Electromagnetic separators, such as the ones used at the Oak Ridge National Laboratory (see Fig. 15), consist of four major components: ion source, accelerating electric field, magnetic field, and collecting apparatus. All are housed in an ultrahigh-vacuum enclosure. Ionic species are affected by the electric and magnetic fields of the spectrometer according to the equation

$$r_0 = \frac{c}{B}\left[\frac{2MV}{e}\right]^{1/2} \tag{62}$$

where r_0 is the radius of curvature of the ion path, c is the speed of light, B is the strength of the magnetic field, M is the mass of the ion, V is the accelerating potential of the electric field, and e is the charge on the ion. Under the same conditions of operation, a change in mass of the ion results in a change in the radius of the path the ion follows. The change can be determined from Equation (62) as

$$\Delta r_0 = \frac{r_0}{2} \cdot \frac{\Delta M}{M} \tag{63}$$

Figure 15. Electromagnetic separator at Harwell
a) Separated isotope collector; b) Vacuum chamber; c) Paths of light ions; d) Paths of heavy ions; e) Ion source; f) High positive voltage; g) High negative accelerating voltage; h) To vacuum pump

If the apparatus is a 180° focusing instrument like that shown in Figure 15, the difference x in the position at which the ions strike the collector is given by

$$x = r_0\,(\Delta M/M) \tag{64}$$

By constructing a large enough collection array and adjusting the electric and magnetic fields, adequate separation can be achieved even for ions with large masses and small mass differences. In theory, an electromagnetic separator should be able to effect the total separation of isotopes of any element; however, the process has practical limitations. The efficient separation power of a given instrument is defined as the largest $M/\Delta M$ ratio obtainable.

The ion source used for large-scale separators is usually a U-shaped tungsten or tantalum filament (the electron source), which is maintained at a negative potential. The source as a whole is maintained at a positive potential. A containing magnet is arranged so that electrons produced by the heated filament pass through the length of the ion source and impact gas molecules introduced into the ion source from a gas cylinder or heated crucible. Positive ions are produced in a complex process by electron collisions and extracted through the slit by a potential difference. The ions are initially accelerated to energies of ca. 60 keV and then decelerated to ca. 30 keV before being allowed to enter the magnetic field of the separator. This acceleration–deceleration sequence isolates the positive ion beam from the source, helps to focus the beam (primary focusing), and provides more uniformity in the energies of the ions. In practice, several different sources are needed if isotopes of a variety of elements are to be separated. The simplest sources are used for gases and very volatile materials; more sophisticated designs are required for higher temperature operation. The Oak Ridge separator has the capability for ion generation at 2000–2800 °C.

Source efficiency is the ratio of singly charged species of the appropriate nuclide leaving the source to the total amount of that species introduced into the source. Losses are primarily due to neutral species being carried out of the source with the ion beam. If the feed is a molecular compound, other ions may be generated by fragmentation to yield charged particles with masses very different from the target ions. For example, separation of uranium isotopes uses uranium tetrachloride (UCl_4) as the feed gas. In addition to U^+ (the desired species for collection), Cl^+, UCl_2^+, and multiply charged ions of these species are also produced. In this case, ca. 25 % of the input molecules are ionized and ca. 70 % of the ionized species are U^+.

Other problems arise because the output from the source is not a tightly focused beam but spreads out over an angle. As the density of the beam increases, the angle of spread becomes larger. Deflection of a diverging ion beam by a homogeneous magnetic field results in impact

on the collection array over a certain length of the array, rather than at a single point. If the beam divergence is defined by an angle $2a$, the maximum spread l of the impact position, called the *focal shift,* is given by:

$$l = r_0 a^2 \tag{65}$$

Large values of a, and hence large values of l, result in overlap of adjacent mass positions in the collection array. Secondary focusing is used to reduce the divergence. The ion beam is deflected into a curved path by a magnetic field in the *tank portion* of the spectrometer. *Shims,* electrically charged metallic strips inserted between the poles of the magnet, generate electric fields that affect the energy of the ions as they pass through the tank.

Two other problems that affect passage of the ion beam are interaction with residual species in the tank and space – charge interactions in the beam. Collisions of ions with molecules in the tank atmosphere can result in *small-angle scattering* and *charge exchange.* Scattering does not prevent ions from reaching the collector but does cause broadening of the beam. In charge exchange, particles lose their charge in a collision but may retain their kinetic energy; these neutral species are not affected by the magnetic field. Efficient evacuation of the tank can reduce these interactions to a large extent, but this also increases the magnetic and electrostatic interactions. This arises from the fact that two equally charged particles traveling along the same path generate magnetic fields, which attract one particle to the other, and electric fields, which have the opposite effect. Magnetic attraction is negligible, but electrostatic repulsion becomes significant as the ion current intensity increases. Repulsive forces tend to broaden the beam and, for production-scale separators, can result in total overlap of target areas by beams of ions with similar masses; isotopic separation is impossible in this case. One method for moderating the electrostatic interaction is to allow collisions with other species in the tank, which leads to formation of negative ions that can separate the positive charges. Such a technique does lead to losses by charge exchange, but an acceptable compromise is to maintain the tank, at ca. 1.3 mPa. Other methods of space – charge neutralization include placing a negatively charged grid or electron-producing device in the path of the ion beam.

The *collection array* is a series of individual pockets that gather and hold the isotopes. These are made of electrically conducting materials and are insulated from one another so that the ion current from each isotope can be monitored. A cover plate with a small slit may be placed in front of each pocket to monitor the focus of the beams. The pockets are deep, narrow boxes, arranged at an angle to the path of the beam so that ions impinge on one side of the pocket and are deflected downward into the box. The ions cannot be decelerated efficiently before they reach the collector, so all the energy of the species must be dissipated within the pocket. Ions that reach the collector may be lost through evaporation from the pocket and through sputtering caused by subsequent ions. Evaporation results from heating of the pocket due to the subsequent impact of ions. The pockets are cooled to prevent distillation of isotopes from one pocket to another and to prevent the pocket from melting. *Sputtering* is the process by which some of the material of the pocket is removed by impact of the ions. The two materials may become intermixed to the extent that another separation step is required to recover the product. Some ions may be sputtered back onto the cover plate or even the cover plate of an adjacent pocket. At large ion energies and throughputs, the life of a pocket may be limited to a few days. With isotopes that are gases under normal conditions, the ions are collected by bombardment of thin metal foils which trap the ions in their surface layers.

The separation efficiency of electromagnetic separators is usually in the 2 – 10 % range. Nevertheless, the technique is valuable because of its adaptability to virtually any element and the fact that small amounts of highly pure isotopes can be obtained. Most elements have been separated by the electromagnetic process, and it is currently used for species that cannot be produced by other methods. The elements are generally grouped by similarities in their properties and the operating conditions needed for separation; these roughly follow the grouping of the periodic table.

Certain gases (Ne, Ar, Kr, Xe, N, O, and CO_2, which is used to separate ^{12}C and ^{13}C) present few problems in source and tank behavior. Collection is limited by the amount of material that can be retained in the foil targets. Alkali and alkaline-earth metals (Li, K, Rb, Ca,

Sr, Ba, and Mg) are processed as the metal or metal halide. Most of these present corrosion problems for the source but are ionized easily, give high current densities, and may be separated in relatively large quantities. Metals (Cu, Ag, Be, Zn, Cd, In, Tl, Sb, Sn, Pb, Cr, Fe, Ni, and Ga) require a medium source temperature and usually employ a halide as the feed material. Problems can arise from plating of the metals on surfaces, which leads to shorting of electrical components. The more volatile elements must be collected in cooled pockets to avoid evaporation. Elements with very volatile chlorides (B, Si, Ti, Ge, Zr, Hf, Ta, Mo, and W) require a low source temperature and sometimes cooling of the source. The metals are refractory and present no problems in collection. Mercury presents special problems because a significant amount of ionized metal may be lost from the source. Gold pockets are often used as collectors to retain mercury by amalgamation. Some elements (e.g., S, Se, Te, Cl, and Br) provide certain problems in collection and require good cooling for efficient retention. The lanthanides (La, Ce, Nd, Sm, Eu, Gd, Dy, Er, Yb, and Lu) are introduced into the source as their chlorides. These materials require a high source temperature (700–900 °C) and may also interact severely with the filament material. Many of these elements have numerous isotopes with closely spaced $M/\delta M$ values, and especially narrow pockets must be used to ensure good separation. Platinum-group metals (Pt, Ru, Pd, and Ir) have very high melting and boiling points and require sources capable of withstanding extremely high temperature. The actinides (Th, U, and Pu) are also used as their chlorides. Sputtering is a problem in collecting these heavy elements. In addition to the separation of naturally occurring isotopes, this technique is well-suited to the separation of artificially produced radioactive species, especially those with short half-lifes.

Large electromagnetic separation production facilities are currently in operation at the Oak Ridge National Laboratory in the United States, at Harwell in Great Britain, and in Denmark, Germany, France, the Netherlands, Japan, South Africa, Russia, and Sweden.

4.2.6. Exchange Reactions

Chemical Exchange. Isotope separation by chemical exchange exploits the equilibrium isotope effect (see Section 2.2.1). The rates of exchange of isotopes between compounds often indicate a preference for association of a particular isotope with one compound rather than another, and this phenomenon may be exploited to enrich that isotope. As shown in Equation (4), the equilibrium constant for an exchange reaction is the ratio of the concentration of the reaction products to the concentration of the reactants. This concentration ratio also defines the elementary separation factor. The factor is a function of the masses of the isotopes involved and is therefore greater for elements with isotopes having the greatest relative mass differences. The isotopes of hydrogen are thus most easily separated by chemical exchange processes. Other isotopes enriched by this technique include those of boron, carbon, nitrogen, oxygen, and sulfur. Many different processes exist for enrichment by exchange reactions which depend on material properties and equilibrium constants. Materials may be brought into contact in the same phase (gas – gas and liquid – liquid processes), in different phases (gas – liquid processes), in distillation processes, at constant temperature (monothermal processes), and by reaction at different temperatures (dual-temperature processes).

Gas – gas reaction processes are used to separate a number of isotopic systems, including the enrichment of ^{13}C by exchange reactions of carbon monoxide and carbon dioxide, and of ^{15}N by exchange reactions involving nitrogen oxides. The most common separation employing this process is the H_2O – HD exchange reaction:

$$H_2O + HD \rightleftharpoons HDO + H_2 \tag{66}$$

The elementary separation factor (equilibrium constant) for this reaction ranges from >4 at 0 °C to ca. 1.2 at 750 °C. For large-scale production, a series of columns, each one a stage, is arranged to form a cascade. The columns, also known as *exchange towers,* are similar to those used for fractional distillation (see Section 4.2.1), with an evaporator at the bottom, a condenser at the top, and bubble-cap plates throughout the tower, connected by downcomer

tubes. In addition to these features are the devices that allow the exchange reaction to take place, catalyst beds between each pair of bubble-cap plates and an electrolytic cell to generate hydrogen.

The electrolytic cell produces hydrogen which is humidified by the evaporator. The gas – vapor mixture passes upward through the column and encounters the first catalyst bed (platinum or nickel alloys) where the exchange reaction enriches the deuterium concentration of the water vapor according to Equation (66). The mixture then passes through the first bubble-cap plate where some of the HDO in the vapor is replaced with H_2O. The new gas – vapor mixture is then directed to the next catalyst bed where the exchange reaction is repeated, passes through the next bubble-cap plate, and proceeds up the tower. Thus, water traveling downward from plate to plate is enriched in deuterium and hydrogen traveling upward is depleted. The water passes on to the refluxing unit of the next stage, whereas the hydrogen is added to the gas flow of the previous stage. A plant with this configuration was constructed in Canada in 1943 and operated until 1956, producing ca. 500 kg of 99.8 % D_2O per month [62, p. 9].

This single-phase separation process is rare. Most of the satisfactory exchange reaction enrichment processes involve two phases (gas and liquid) or two immiscible liquids. For such a system to be practical, several criteria must be met. The two compounds involved in the exchange reaction should each be present in only one of the phases, e.g., in the enrichment of ^{15}N by exchange between nitric acid (liquid) and nitric oxide (gas). The exchange should be rapid or capable of being catalyzed so that short exchange towers can achieve a high degree of enrichment. The equilibrium constant for the exchange should be as large as possible to reduce the number of stages required in the cascade. This implies that the isotope of interest should be weakly bonded in one of the compounds and strongly bonded in the other, a situation which is at odds with rapid exchange (an isotope weakly bonded in both compounds would have the fastest exchange rate). Finally, the system should be able to support total reflux, in the sense that the liquid phase is converted to the gas phase by chemical reaction, rather than boiling, in each stage to achieve maximum interaction of the two phases.

Separation of ^{15}N by means of the reaction

$$^{15}NO + H^{14}NO_3 \rightleftharpoons {}^{14}NO + H^{15}NO_3 \tag{67}$$

is a good example of a gas – liquid exchange process [73]. Separation can be accomplished in a packed column. The exchange reaction is rapid and is catalyzed by nitrous acid. An enrichment of ^{15}N from 0.36 to 99.6 % has been achieved by using two columns of 3.0- and 1.5-cm diameter. At the bottom of each column, nitric acid is converted to nitric oxide by reduction with sulfur dioxide. The gas flows upward through the packed bed and exchanges the heavier isotope, as shown in Equation (67). The gas reacts with oxygen and is absorbed into water at the top of the column to regenerate nitric acid, which flows downward in the column.

A liquid – liquid exchange process has been developed for the enrichment of ^{6}Li [74]. This process involves the exchange of lithium isotopes between a liquid lithium amalgam and a solution of lithium chloride in absolute ethanol. Amalgam is fed dropwise into the top of the 18-m column containing the solution and participates in the reaction

$$^{7}LiHg + {}^{6}LiCl \rightleftharpoons {}^{6}LiHg + {}^{7}LiCl \tag{68}$$

At the bottom of the column, the lithium amalgam is converted to lithium chloride by hydrogen chloride in alcohol solution. To avoid violent reactions with metallic lithium, a neutral solution must be maintained and water must be rigorously excluded. The actual separation factor was not determined in this system because each droplet of the amalgam did not follow the same path through the solution and it was not known whether equilibrium was achieved. The process operated in a discontinuous mode. Each batch required ca. 24 h for processing and was enriched in ^{6}Li by a factor of slightly more than 2.

As stated, one criterion for an acceptable exchange reaction separation process is the availability of a reflux method that allows the two phases or liquids to be readily interconverted, ideally in a quantitative manner. Not all isotopic systems with large equilibrium constants are amenable to the electrolytic or chemical oxidation and reduction reactions used with the sample systems discussed here. Another method, *exchange distillation,* may be employed in some

cases. In this technique, however, enrichment does not rely on the difference in vapor pressures of the isotopic species. Instead, the liquid being distilled dissociates in the vapor phase to give a material with different composition. The separation of boron isotopes uses such a process [63]. The liquid phase is the dimethyl ether adduct of boron trifluoride, which dissociates to the uncomplexed compound upon distillation. The exchange reaction is thus given by the equations

$$BF_3 \cdot O(CH_3)_{2(l)} \rightleftharpoons BF_{3(g)} + O(CH_3)_{2(g)} \tag{69}$$

$$^{10}BF_{3(g)} + {}^{11}BF_3 \cdot O(CH_3)_{2(l)} \rightleftharpoons {}^{11}BF_{3(g)} + {}^{10}BF_3 \cdot O(CH_3)_{2(l)} \tag{70}$$

The process operates in a packed fractionation column. The etherate is boiled in an evaporator at the bottom of the column, and the dissociated vapor passes upward through the column. The adduct is reformed in a condenser at the top of the column. The exchange reaction takes place between the liquid etherate and boron trifluoride gas on the surface of the packing material. Separation factors for columns used in this exchange are ca. 1.02. The process was first developed in 1944 in connection with the Manhattan Project to supply a large quantity of boron (50 kg) enriched to 90 % in ^{10}B. The process was classified by the U.S. government until 1957, and in the meantime, was developed in Sweden and Great Britain in the 1950s.

Another method is available to avoid problems associated with refluxing a two-phase system. The *dual-temperature process* employs two columns operating at different temperatures and, therefore, having different equilibrium constants for the exchange reaction [75]. In one column, one phase of the system is enriched at the expense of the second at a given temperature to provide the desired product. In the other column, the depleted phase from the first column is enriched by exchange with the first phase at a different temperature. The second phase from this column is then used as the feed for the first column. Figure 16 shows a dual-temperature arrangement for the production of heavy water by exchange with hydrogen sulfide gas. The two columns together constitute a stage, and several stages are arranged to form a cascade. The reaction for this process is given by

$$H_2O_{(l)} + HDS_{(g)} \rightleftharpoons HDO_{(l)} + H_2S_{(g)} \tag{71}$$

The choice of operating conditions for the process must take several factors into account. The temperatures of the two columns are selected so as to maximize the difference between the equilibrium constants. However, the upper temperature that can be used is limited by the increasing corrosivity of H_2S at high temperature. High-pressure operation is desirable to minimize the column cross-section, but formation of a solid hydrate of H_2S at low temperature and liquification at high temperature restrict the maximum pressure. A successful compromise is to operate the columns at 30 and 130 °C and 2 MPa pressure.

The equilibrium constant (elementary separation factor) for the reaction at 30 °C is 2.3, whereas at 130 °C it is 1.8. The upper (cold) column is operated at the lower temperature and fed with a flow of ordinary water (for the first stage in the cascade; successive stages are fed with product from the previous stage). Deuterium is exchanged from hydrogen sulfide to water as the gas bubbles through successive plates of the column. At the bottom of this column, some water is withdrawn as product and is passed to the next stage in the cascade. The remainder of the water is heated in a heat exchanger, mixed with additional water from the stage immediately downstream in the cascade, and passed to the hot column below. The depleted hydrogen sulfide, removed at the top of the cold column, is also heated and then introduced at the bottom of the hot column. As it flows upward through the plates of this column, hydrogen sulfide becomes enriched in deuterium at the expense of water. The enriched gas is then cooled and fed into the upper column to repeat the enrichment of water there. Water from the hot column, depleted in deuterium, goes to a heat exchanger where it is used to heat water entering this column and is then directed to the next column upstream in the cascade to make up part of the feedwater for the hot column of that stage. Thus, the refluxing requirement of the process is met by the two different equilibria of the hot and cold columns.

The enrichment factor α for this particular arrangement of columns and flows in the cascade depends on the equilibrium constants and the cut θ, the portion of water leaving the upper column that is directed to the next stage of the cascade:

Figure 16. A) Dual-temperature exchange column; B) Cross section through cold column
a) Cold column, temperature 30 °C, $K = 2.3$; b) Heat exchanger; c) Hot column, temperature, 130 °C, $K = 1.8$

$$\alpha = 1 + \frac{K_1 - K_2}{K_1} \cdot \frac{1-\theta}{\theta} \tag{72}$$

where K_1 and K_2 are the equilibrium constants for the lower and higher temperatures, respectively. The enrichment factor can be large at small values of the cut. Dual-temperature chemical exchange on a production scale has been implemented only for the enrichment of deuterium. Other isotopic systems do not show the large equilibrium isotope effect that is found for protium and deuterium and, consequently, do not have large enough differences in equilibrium constants as a function of temperature to make the technique viable for isotope separation. In addition to the water – hydrogen sulfur process described, other systems that allow deuterium enrichment by the dual-temperature process include water – ammonia, water – hydrogen halides, water – hydrogen, and ammonia – hydrogen.

Ion-Exchange Processes. A different type of chemical exchange technique is employed in ion-exchange processes, sometimes referred to as *chromatographic separation* [76]. Instead of two phases moving countercurrent to one another, ion-exchange methods use columns in which one phase is stationary and a second phase moves through the column. The countercurrent aspect of separation is achieved even with one stationary phase because the species to be separated move through the column and interact with both phases continually.

An example of ion-exchange separation is the enrichment of ^{15}N by interaction of a dilute aqueous ammonia solution with a cationic exchange resin that incorporates sulfate groups on the surface of the resin particles. The resin is first washed with acid to saturate all of the sulfate groups with protons. A quantity of ammonia solution is added to the column and reacts with the resin:

$$\text{Resin-H} + NH_4OH \rightleftharpoons \text{Resin-}NH_4 + H_2O \tag{73}$$

Thus, a portion of the resin is in equilibrium with the solution. The length of solution in contact with the resin, called a *band,* is determined by the size of the charge applied; the front end of the band is sharply defined because of the large equilibrium constant for the reaction between

solution and resin (in this case ca. 10^9). To create flow through the column, a solution of sodium hydroxide is added to the column above the band of ammonia solution. Another reversible reaction between the resin and this solution takes place according to the equation

$$\text{Resin-NH}_4 + \text{NaOH} \rightleftharpoons \text{Resin-Na} + \text{NH}_4\text{OH} \tag{74}$$

The large equilibrium constant for this reaction (10^5) sharply defines the rear of the band. More hydroxide is added to move the band containing the ammonia solution down the column. As the front of the band encounters new resin, the exchange reaction continues, whereas at the rear of the band, ammonium ions are continually returned to the band through displacement by sodium hydroxide, keeping the band at constant size as it moves along the column. This method of separation is known as *displacement* because the target ions absorbed onto the resin are displaced by other ions.

The separation of isotopes occurs as a result of equilibrium isotope effects in Equations (73) and (74). The exchange of ammonium ions with protons on the column results in a small enrichment of ^{15}N in the bound species, whereas the release of ions by sodium hydroxide gives a much larger separation of the isotopes. The overall result of these reactions is that the ammonium ions at the rear of the band are enriched in the heavier isotope and the front of the band is depleted in that species. The elementary separation factor for the process is given by the product of the ratios of the concentrations of the two isotopic species in their various forms:

$$q_0 = \frac{[^{14}\text{NH}_4\text{OH}]\,[^{15}\text{NH}_4\text{-resin}]}{[^{15}\text{NH}_4\text{OH}]\,[^{14}\text{NH}_4\text{-resin}]} \tag{75}$$

Other methods of chromatographic separation are the *elution technique* and the *breakthrough technique.* In the former, the column is washed with a solution containing a compound of the isotopes to be separated, and some of the compound is allowed to be absorbed on the resin. Another solvent is then passed through the column, and the compound is desorbed into the new solvent. If the properties of the isotopically substituted species are such that their desorption equilibria differ, the front of the band containing the desorbed species is enriched in one isotope and the rear of the band in the other. In the breakthrough technique, a difference in the absorption equilibria of the isotopically substituted species is used in the same way. A solution containing two species is passed through the column, and the material that is absorbed least strongly is concentrated at the front of the column.

An advantage of ion-exchange methods for isotope enrichment is that they may be applied to virtually any isotopic system with the right combination of resin and solvents. Exchange processes have been used effectively to separate isotopes of lithium, boron, sodium, sulfur, calcium, and uranium. Gas chromatography has been used to enrich isotopes of hydrogen and neon. Gaseous isotopes are separated by their different rates of absorption and desorption on a suitable material, (e.g., palladium or charcoal). An interesting effect is achieved in the separation of hydrogen isotopes over activated alumina. Not only are H_2, HD, and D_2 collected individually, but the *ortho* and *para* isomers of both H_2 and D_2 are also separated. Another advantage of ion exchange is the relatively high density of the stationary phase (the resin particles can be manufactured with very high ratios of surface area to volume). Thus, the height equivalent of a theoretical plate may be very small (ca. 1 mm or less) compared to other processes such as distillation in a packed column (HETP = ca. 0.5 m); therefore, columns can easily be prepared with tens or hundreds of plates.

Disadvantages of the process include the fact that the process is discontinuous because one phase is stationary and material must be processed batchwise. Furthermore, only a limited number of plates are in contact with the band of material as it passes through the column, and as little as 6 % of the effective area of the exchange resin may be involved in the enrichment at any one time. These problems can be reduced somewhat by introducing a second charge before the first has left the column, a technique that can be repeated several times before the resin must be totally regenerated. A more serious disadvantage arises from the long time needed to reach equilibrium between solid and liquid phases. A compromise is necessary between the rapid collection of isotopes and the lower enrichment resulting from operating further from equilibrium conditions. If the mobile phase is a gas or if the exchange reactions of species in a mobile liquid phase have a relatively high equilibrium

constant, these difficulties are reduced. The ion-exchange process is particularly suited for the production of laboratory quantities of light isotopes.

4.2.7. Photochemical Separation

The difference in mass between isotopes results in differences in their optical spectra, both in the elemental form and in compounds containing them (see Section 2.1.1). Photochemical separation of isotopes takes advantage of the different energies of various transitions to ionize or otherwise excite one isotope selectively. Thus, the process holds great promise of achieving a very large elementary separation factor. Several criteria must be satisfied for this potential to be realized: (1) the isotopic species must have well-defined absorbance differences as a consequence of the isotopic effect; (2) the exciting energy must be limited to a range that affects only the species of interest; (3) the modes of energy exchange from the species of interest to other isotopes must be slow compared with the process used to remove the excited species from the mixture of isotopes; (4) the excitation energy must be intense enough to give a good yield; and (5) extraction of the excited species from the isotopic mixture should be rapid, selective, and quantitative.

The first successful photochemical isotope separation was achieved in 1958 by Gunning, who enriched ^{202}Hg from its natural abundance of ca. 30 % to more than 90 % [77]. The process involved excitation of the specific isotope by irradiation in the area of the 253.7-nm absorption band of mercury. The excitation energy was selectively filtered by passing it through mercury vapor that had been depleted in ^{202}Hg by another means. In the presence of oxygen, the excited species reacts to give $^{202}HgO_2$, with an oxidation rate orders of magnitude faster than that of the unexcited mercury isotopes. The oxide was stabilized by addition of butadiene and removed from the reaction mixture. Similar methods for separating other mercury isotopes are of interest because of their potential for use in fluorescent lighting (see Section 3.4).

Photochemical reactions have also been explored for separation of uranium isotopes. Ionization of metallic uranium in the vapor phase and dissociation of gaseous UCl_6 to form UCl_5^+ have been accomplished with laser excitation. The charged species are removed from the isotopic mixture by collection on a negatively charged plate. Laser sources appear to be ideal because they can be tuned with precision to narrow energy bands. Scaleup of this process is currently hampered by difficulties in handling large quantities of molten uranium and by secondary reactions that reduce the selectivity of the excitation process; nevertheless, it promises to allow uranium enrichment at a substantially lower cost than gaseous diffusion.

4.2.8. Electrolysis

Separation of isotopes by electrolysis is based on the difference in rates of production of an element by oxidation or reduction of an ionic species [78]. Many elements exhibit isotopic effects upon electrolysis, but hydrogen has by far the largest rate difference between isotopes. Separation effects have been reported for isotopes of nitrogen, oxygen, and chlorine (among others), but all have elementary separation factors close to 1.0, whereas the factor for hydrogen enrichment by electrolysis of water (containing an electrolyte such as potassium hydroxide or potassium carbonate) ranges from ca. 3 to >17, depending on temperature and other conditions.

No definitive theory can explain the difference in rates for different isotopes. With hydrogen, the need for a greater overvoltage (the voltage above the reduction potential actually necessary to generate the element at the cathode) for deuterium appears to make its rate of production slower than that of protium. Various experimental studies have cited different steps as rate determining, including discharge of the ion at the electrode, formation of the molecular species from the atoms, and exchange of isotopes between water molecules adsorbed onto the cathode surface and those in solution. Despite this ambiguity, the elementary separation factor can be determined experimentally by simply comparing the relative abundance of deuterium in the water with its relative abundance in the gas produced at the cathode. Several factors influence the value of the separation factor. The temperature of the electrode during electrolysis is a major influence; the separation factor increases

as temperature decreases. The ion current is important because it affects electrode temperature; high current densities may heat the electrode faster than the surrounding solution can dissipate energy. The cathode material affects the separation of hydrogen and the overvoltage needed to cause reduction in ways that are not completely understood. Some of the differences in separation factor can be attributed to the catalysis of exchange reactions by certain materials, which alters the isotopic abundance of the species reacting or formed at the electrode. In general, materials requiring a higher overvoltage give lower separation factors, but this is only a qualitative observation and many exceptions have been reported.

The use of electrolysis for the production of highly enriched deuterium from water at natural deuterium concentration is not economically viable. As an adjunct to hydrogen production plants for other purposes (e.g. fertilizer synthesis) the added expense of separating deuterium-containing species may be warranted. This type of arrangement yields only small quantities of heavy water; a 300 t/d ammonia plant would produce only 24 t of D_2O per year. Another practical use of electrolysis is the final enrichment of deuterium that has been highly enriched by another process. Production of heavy water for the Manhattan Project was accomplished in such a manner. The distillation plant at Morgantown (see Section 4.2.1) used electrolysis to enrich water from a deuterium content of 88 – 92 % to ca. 99.9 %. The process was reversed in Canadian and Indian facilities, with electrolysis producing enriched feed material for distillation. These separation operations are associated with ammonia production plants.

Most often, electrolysis is operated as a batch process. A charge of water is placed in a cell and electrolyzed until the material remaining in the cell has the desired deuterium abundance. This allows greater flexibility in accommodating feed materials of different isotopic abundances. Such facilities are generally easier to construct and operate but are more labor intensive and increase the possibility of material losses.

Continuous processes involve a cascade with a number of stages, depending on the desired final deuterium concentration, and may be of the recycling or nonrecycling type. In a nonrecycling system, hydrogen and oxygen (produced at the anode) are drawn off and used for other purposes. A recycling system burns the gases to form water, which is then added to an upstream stage. Such cascades are usually designed in a square configuration (see Section 4.1.2). The flow from stage to stage is in the form of steam that accompanies production of the gases. Instead of burning the hydrogen produced by electrolysis, the yield of the continuous process can be increased by incorporating a chemical exchange system in the recycling portion of the cascade. This recycling operation takes the hydrogen and steam, which accompany gas production (steam that has a higher deuterium concentration than the gas), from a separation unit and passes them through a scrubber column. A countercurrent flow is established with water coming from an earlier stage in the cascade. In the scrubber, water is enriched in deuterium at the expense of steam and passes to the next electrolytic cell in the cascade. Steam, depleted in deuterium, is condensed and fed into the exchange reaction chamber of the same stage along with hydrogen. Here, the equilibrium isotope effect enriches the deuterium concentration of water at the expense of hydrogen. The water is then returned to the electrolytic cell of the stage from which it came, whereas the hydrogen is used to make up part of the gas stream entering the scrubber column of the stage immediately upstream. Some heavy-water production facilities use a combination of recycling processes. An electrolytic plant in Norway employs scrubbers and exchange reaction chambers in the first section to help achieve a 2 % enrichment of deuterium. The remainder of the facility, which increases the concentration to ca. 15 %, employs burning of hydrogen for recycling.

Electrolysis also concentrates tritium in the liquid phase. The separation factor for enrichment of tritium is higher than that for deuterium and tritium may be present in measurable quantities in highly enriched heavy water.

4.2.9. Electromigration

Another phenomenon that occurs during electrolysis–electromigration–can be used to separate isotopes. Instead of relying on the difference in the rate of production of isotopes in their elemental form, electromigration depends

on the different mobilities of the ionic species as they move toward the electrodes of the cell. The separation effect is, theoretically, determined by the ratio of the migration rates of the light and heavy isotopes of an element, but it may also be affected by thermal gradients and back diffusion of ions in the solution or melt being electrolyzed. Elementary separation factors are similar to those for electrolysis, close to 1.0 for most elements. The process was successfully applied to the separation of ^{39}K and ^{41}K in the late 1940s, and to ^{6}Li and ^{7}Li thereafter. The apparatus for electromigration consists of a tube that holds a molten salt, a molten salt eutectic, or a solution of the salt containing the isotopes to be separated. Electrodes at either end of the tube are given a potential difference great enough to cause oxidation and reduction of ionic species in the tube. Migration toward the appropriate electrode enriches the lighter isotopic species in its vicinity and depletes it near the opposite electrode. Because the production of elemental species is not necessary, some method of regenerating the ionic species is employed at each electrode.

In the separation of potassium isotopes an aqueous solution of potassium chloride is electrolyzed [79]. The lighter ^{39}K is concentrated at the cathode; any metallic potassium produced by reduction is allowed to react with hydrochloric acid to maintain a constant total ionic concentration. Oxidation of chloride ions at the anode is reversed by addition of potassium hydroxide. Because potassium hydroxide also contains potassium isotopes in their natural abundance, collection of enriched ^{41}K is not possible. A porous filter isolates the electrodes and the solutions adjacent to them from one another and prevents contamination of the enriched ^{39}K near the cathode. In the separation of lithium isotopes, molten lithium chloride is used instead of an aqueous solution. Chlorine gas is added to reduce metallic lithium formed at the cathode. The desired product ^{7}Li is concentrated near the anode because ^{6}Li migrates toward the cathode at a higher rate. A buffer solution, a compound whose cation is not electrolyzed at the potential used (e.g., $PbCl_2$), is employed to isolate the lithium chloride melt from the anode. An abundance of 99.9 % for ^{7}Li has been achieved by this process. The technique is not economical for large-scale separation of isotopes but can provide small quantities of enriched isotopes for laboratory work.

4.2.10. Other Separation Processes

Several new technologies for enrichment of isotopes are in various stages of development [80], and not enough information is available to describe them in detail. *Vacuum arc centrifugation* (VAC) uses magnetic fields to rotate a beam of ions containing the isotopes to be separated. The separation efficiency is related to the difference in the masses of the isotopes and the rotation frequency of the plasma. VAC is said to be applicable to a wide range of isotopes and could produce them in kilogram quantities. The *solitron* also separates isotopes in an ion beam, in this case by imposing a traveling electric field wave on the beam. This device is expected to be essentially portable and produce a variety of isotopes for research purposes. The *SILEX process* is a proprietary laser separation process under development in Australia that appears to be based on excitation of molecular species containing the isotopes of interest.

5. Availibility

Stable isotopes are available from a large number of companies. A significant part of the market for stable isotopes includes isotopically labeled organic compounds, typically used in diagnostics and research. With the approval of medical diagnostic tests using labeled compounds, the production of isotopically labeled compounds will likely see a large increase. The most common isotopes for labeling are deuterium and ^{13}C, with ^{15}N and ^{18}O also readily available. Compounds such as amino acids, carbohydrates, nucleosides, and pharmaceuticals are marketed with partial or complete substitution. Noble gases and metal isotopes are other important categories of commercially available isotopically enriched materials. Most isotope suppliers have custom synthesis capabilities for manufacture of uniquely substituted compounds. Radioisotopes, produced from stable isotopes by neutron irradiation, are also available from commercial and government sources.

Canada and Russia supply the overwhelming majority of radioactive isotopes at this time.

The U.S. Department of Energy national laboratories produce and sell both stable enriched isotopes and radioisotopes to fill needs where private sector capability is nonexistent or is insufficient to meet U.S. demand. Brookhaven, Los Alamos and Oak Ridge National Laboratories have facilities for target irradiation and will lease the use of hot cells for separation of radioisotopes produced at the laboratories. DOE's New Brunswick Laboratory produces standards and references for thorium, uranium, and plutonium.

A partial list of companies offering enriched stable isotopes and/or radioisotopes for sale includes:

Associated with the rise in the use of isotopes for research and medicine and their potential use in industry is an increase in the number of facilities for the analysis of isotopic composition. Many universities have isotope laboratories associated with research programs that employ stable or radioactive isotopes and will perform such analysis for other customers as well. Many of the suppliers of isotopes also market the capability to perform analyses.

1. Introduction

Ketenes are described by the general formula $R^1R^2C{=}C{=}O$. Of commercial and industrial importance are mainly the lowest member of this class, ketene itself, $H_2C{=}C{=}O$, and its dimer, diketene. The latter has attained a prominent role in industrial synthetic chemistry. Ketene and diketene lend themselves to a number of useful conversions because of their multifunctionality.

The parent substance, monomeric ketene, was first prepared in 1907 by Wilsmore by immersing a glowing platinum wire in liquid acetic anhydride. Staudinger subsequently described its preparation by the reaction of bromoacetyl bromide [*598-21-0*] with zinc. The first industrial use of ketene appeared in the 1920s, when larger quantities of acetic anhydride were required for the production of cellulose acetate.

2. Ketene

2.1. Physical Properties [1–13]

Ketene [*463-51-4*], $CH_2{=}C{=}O$, C_2H_2O, M_r 42.02, is a colorless, toxic gas with a characteristic odor; it is unstable at room temperature and atmospheric pressure. Ketene is very soluble in acetone and lower esters; it is only slightly soluble in hydrocarbons and halogenated hydrocarbons.

Some important physical properties of ketene follow:

mp	− 150 °C
bp at 101.3 kPa	− 49 °C
Vapor pressure at − 120 °C	0.53 kPa
− 71 °C	19.5 kPa
20 °C	1.9985 MPa
30 °C	2.6355 MPa
40 °C	3.4137 MPa
50 °C	4.3506 MPa
90 °C	10.0253 MPa
Density	
gas	1.93 g/cm^3
liquid (− 60 °C)	0.650 g/cm^3
Vapor density (theoretical, air = 1)	1.45
Free energy of formation, ΔG_f^0	-46.9 ± 1.6 kJ
Enthalpy of formation, ΔH_f^0	− 47.7 kJ
Dipole moment	1.41 D

Crude ketene, as obtained from the cracking of acetic acid and used industrially, contains ca. 8 vol % acetic anhydride and 7 vol % inert gases (mainly carbon monoxide, carbon dioxide, ethylene, and methane). Ketene from the cracking of acetone also contains a stoichiometric amount of methane.

2.2. Chemical Properties [1–13]

Ketene is an extremely reactive and unstable compound: it dimerizes to diketene and polymerizes very quickly. The 4-methyleneoxetan-2-one structure of diketene was established in 1952 by X-ray diffraction [15]. Under the conditions for the industrial production of diketene, less than 5 % of ketene dimerizes to 1,3-cyclobutanedione in its monoenolic form, which in turn is further acetylated. It can only be stored at liquid nitrogen temperature. To prevent polymerization, reactions with ketene are best conducted under reduced pressure. If this is not possible, the reaction vessel should be directly connected to the ketene source or compressor.

To avoid formation of acetic acid and acetic anhydride, reactions with ketene should be carried out in a dry atmosphere, but because it does not form peroxides (in contrast to the ketoketenes) ketene does not require an oxygen-free atmosphere.

The main reactive center in ketene is the carbonyl carbon atom, which is strongly electrophilic. Consequently, ketene reacts readily with nucleophiles. The electronic structure of ketene can be described by the following canonical forms:

More modern interpretations use a molecular orbital approach [11].

Ketene preferentially undergoes addition reactions with substances containing polar or easily polarized single or multiple bonds. Addition usually takes place across the C=C double bond, and the oxygen atom is seldom involved. In the absence of other reaction partners, ketene adds a second molecule of ketene to form diketene. The main types of reactions that ketene participates in are acetylation, cycloaddition, ketene insertion, and polymerization.

Acetylation. Compounds with a reactive hydrogen atom are acetylated by ketene:

Ketene acetylates substances containing hydroxyl groups, e.g., water is acetylated to acetic acid, aliphatic alcohols to alkyl acetates, phenols to aryl acetates, carboxylic acids to anhydrides, enols to enol acetates, hydrogen peroxide to diacetyl peroxide, and hydroperoxides to peracetates. Acidic and basic catalysts strongly increase the reaction rate [16]. Metal salts are also effective catalysts [17].

Sulfur analogues react with ketene similarly: hydrogen sulfide is acetylated to thioacetic anhydride via thioacetic acid, and aliphatic thiols yield alkyl thioacetates. Hydrogen halides give the corresponding acetyl halides. The reaction with hydrogen sulfide requires a catalyst; other sulfur compounds do not necessarily require catalysis.

Ketene reacts with ammonia, primary and secondary amines, amides, imides, hydrazines, hydrazones, ureas, and azomethines to give the corresponding monoacetates; sometimes the di- and triacetates are also formed. With strong bases the reaction can be quite violent. For weakly basic or substituted NH groups, acids or amides are recommended as catalysts [18]. Ketene can selectively acetylate amino groups in the presence of hydroxyl groups. Examples are the acetylation of ammonia [1, p. 124] and the *N*-acetylation of ethanolamine in aqueous solution. Alcohols or even water can be used as solvents for such reactions.

Cycloadditions. Substances bearing a double bond (e.g., C=C, P=N, C=X, or N=X, where X = O, N, or S) can undergo [2 + 2] 1,2-cycloaddition with the ketene C=C bond. This synthetically useful reaction leads to versatile four-membered rings:

A catalyst is often necessary. Ketene itself does not react with nonpolar olefins (ketoketenes and halogenoketenes are more reactive), but it does react with 1,3-dienes and active olefins such as vinyl ethers, vinyl esters, enamines, alkoxyacetylenes, and allenes. Carbonyl compounds, especially those with electron-withdrawing groups, give 2-oxetanones (β-lactones). The dimerization of ketene to diketene falls into this category.

Optically active 2-oxetanones have been obtained with chiral tertiary amines as catalyst

in cycloadditions with electron-deficient aldehydes and ketones [19]. Electron-rich aldehydes give chiral β-lactones when a chiral Lewis acid is used [20]. Thietanones are obtained from thiocarbonyl compounds; nonenolizable imines (azomethines) give 2-azetidinones (β-lactams) [21], [22]. 1,3- and 1,4-cycloadditions are also known, though rare; an example follows (yield ca. 16 %):

For a review of cycloadditions with ketenes see [1], [8], [11], [13], [23].

Recent work has shown that some 1,2-cycloadditions are in fact 1,4-cycloadditions to the C–O bond followed by a 1,3-Claisen rearrangement [24].

Ketene Insertion. Substances with strongly polarized or polarizable single bonds add to the ketene C=C double bond in a reaction known as ketene insertion:

Thus, active acyl chlorides with an electron-withdrawing substituent (e.g., CCl_3 or CF_3) give the corresponding 3-ketoacyl chlorides, phosgene inserts two moles of ketene to yield acetone dicarboxylic acid dichloride [25], and α-haloethers give 3-oxa-substituted propionyl halides. Acetals and ortho-esters with Lewis acid catalysis give β-alkoxy carboxylic esters [26].

Other insertion reactions take place with chlorine (to give chloroacetyl chloride), bromine, thionyl chloride, and with mineral acids.

Polymerization of ketene with various catalysts can give either polyesters (**1**) or polyketones (**2**); higher ketenes also give polyacetals (**3**) [27].

1 **2** **3**

Ketene equivalents, such as the stable trimethylsilylketene, have been described for synthetic use [28], [29].

Reduction of ketene with Pd/H_2 to give acetaldehyde and/or vinyl acetate allows the production of these intermediates directly from a syngas (CO/H_2) source [30].

2.3. Production

Ketenes are the internal anhydrides of the corresponding carboxylic acids, and as such can be made by removing a molecule of water from these acids, either directly or indirectly. Numerous methods have been used to convert a precursor to the corresponding ketene [8], [9], [11], [13].

Ketene is produced by *pyrolysis of acetic acid* [*64-19-7*], which, although endothermic, is quite an efficient process. Decomposition products formed in the pyrolysis of acetic acid to ketene include methane, hydrogen, carbon monoxide, carbon dioxide, and ethylene. Higher acids can also be cracked to the corresponding ketenes, although the efficiency of conversion decreases as the chain length increases. The corresponding carboxylic anhydrides give better results [31], [32]. Long-chain alkylketenes are made industrially from the corresponding fatty acid chlorides. Ketene generators and ketene reaction apparatus for both the laboratory and production scale have been reviewed [33].

High-quality acetic acid is evaporated and the vapor passed continuously through a radiant coil under reduced pressure at 740 – 760 °C. Triethyl phosphate [*78-40-0*] catalyst is injected into the acetic acid vapor. Ammonia is added to the gas mixture leaving the furnace to prevent ketene and water from recombining and to neutralize the catalyst. The gas mixture is chilled to < 100 °C to remove water, unconverted acetic acid, and the acetic anhydride formed as a liquid [34], [35]. The gaseous ketene is absorbed in the appropriate reaction medium or dimerized in a liquid ring pump (liquid seal pump) if diketene is the desired reaction product. The medium consists of a liquid substance or a solution of a compound that is to be treated with ketene (e.g., alcohols, amines, and thiols). Diketene itself is

the preferred dimerization medium for ketene. The crude ketene gas is at a pressure of 20–30 kPa before entering the dimerization unit. It can therefore only be used for reactions with higher boiling reactants that will not vaporize at this pressure. In the case of more volatile reactants or when a higher reaction temperature is required, the crude ketene is compressed to ambient pressure. This is best done in a liquid ring pump by using a liquid in which ketene is only sparingly soluble (e.g., decalin) [36].

A useful laboratory-scale synthesis of high-purity ketene has been described [37]. This method, which gives very pure ketene by *pyrolysis of diketene*, can also be employed on an industrial scale. Thus, a convenient and technically feasible process for producing pure ketene, uncontaminated by methane and other hydrocarbons and oxides, is available. Conversion of diketene to monomeric ketene is accomplished on an industrial scale by passing diketene vapor through a tube heated to 350–600 °C:

The pyrolysis of dimeric ketenes, whether in the β-lactone or cyclobutane-1,3-dione form, is a general method for obtaining pure ketenes in high yield.

Ketene can also be generated on an industrial scale by *thermal decomposition of acetone or acetic anhydride.* Nevertheless, the former is only interesting as a raw material when the price is low.

2.4. Uses

Ketene, the internal anhydride of acetic acid, is a powerful acetylating agent (see Section 2.2). It reacts generally at the C=C double bond with compounds containing an active hydrogen atom to give an acetyl derivative:

Production of Acetic Anhydride. Most of the ketene produced worldwide is used in the production of acetic anhydride (see also → Acetic Anhydride and Mixed Fatty Acid Anhydrides, Chap. 1.3.).

In the early 1980s, the Tennessee Eastman Company developed a new process for the coal-based production of acetic anhydride by carbonylation of methyl acetate [*79-20-9*] [38]. This process has economic advantages in times of high oil prices.

Production of Diketene. The second most important industrial use of ketene is the production of diketene by controlled dimerization (see Section 3.2).

The incorporation of the acetoacetate moiety into pigments, pharmaceuticals, and agricultural chemicals is an important area of synthetic chemistry.

The diketene–acetone adduct is a nonlachrymatory liquid which can be safely handled at room temperature.

Production of Sorbic Acid. The third major use of ketene, albeit less important than the first two mentioned above, is in the production of sorbic acid [*110-44-1*] [39], [40], [41]. Reaction of ketene with crotonaldehyde [*123-73-9*] gives, depending on the conditions, either the β-lactone **4** or the polyester **5**. Both products can be converted, thermally or by acidic catalysis, to sorbic acid:

The corresponding reaction of ketene with formaldehyde, once an important use of ketene in the production of acrylates via propiolactone,

is no longer used on a commercial scale because the intermediate β-propiolactone [*57-57-8*] (2-oxetanone) is a suspected carcinogen.

The most economical process for the production of acrylates is now based on the two-stage vapor-phase oxidation of propene to acrylic acid [42] (see also → Acrylic Acid, Chap. 1.3.).

Production of Chloroacetyl Chloride. Chlorine adds to ketene to form chloroacetyl chloride [*79-04-9*] [43]:

Chloroacetyl chloride has varied industrial uses, such as the production of herbicides of the alachlor type and local anesthetics of the lidocaine type.

4,4,4-Trihaloacetoacetates. In the presence of strong Lewis acids such as boron trifluoride, appropriately substituted acyl chlorides add to ketene to form the corresponding acetoacetyl chlorides, which can then be treated with an alcohol to form the corresponding haloacetoacetates.

Of industrial significance are ethyl 4,4,4-trifluoroacetoacetate [*372-31-6*] for the production of herbicides and antimalarial agents, and ethyl 4,4,4-trichloroacetoacetate [*3702-98-5*] for the production of pharmaceuticals.

Isopropenyl Acetate and Acetylacetone. Acetone, like other carbonyl compounds containing active hydrogen atoms, undergoes enol acetylation on reaction with ketene; a strong acid catalyst is required. The isopropenyl acetate [*108-22-5*] formed [44], [45] is the starting material for the production of acetylacetone [*123-54-6*], which is an intermediate for the sulfa drug sulfamethazine [*57-68-1*].

The reaction of acetone with ketene with Lewis acid catalysis gives 4,4-dimethyloxetan-2-one [*1823-52-5*], which is used to produce the food-additive calcium 3-hydroxy-3-methylbutyrate [*135236-72-5*] [46].

Chiral Lactones. Chloral and 1,1,1-trichloroacetone react with ketene to form the corresponding 4-trichloromethyloxetanones. In the presence of an optically active catalyst, chiral lactones are obtained [19], [47], [48].

The synthesis of chiral β-lactones [49–51] has assumed greater importance due to pharmaceutical activity found for some β-lactone structures [52].

Cinnamic Esters. The insertion reaction of ketene with *p*-methoxybenzaldehyde [*2186-92-7*] is used to produce 2-ethylhexyl *p*-methoxycinnamate [*5466-77-3*], a sunscreen used in cosmetics [53] (see top of the next page).

3. Diketene

3.1. Physical Properties

Diketene [*674-82-8*], $C_4H_4O_2$, M_r 84.04, is a colorless liquid when pure; it possesses a pungent odor and is a strong lachrymator. The human odor perception threshold is 0.019 mg/m^3 [54].

Crude diketene obtained from the dimerization of ketene is often used without further purification; it is dark brown and contains up to 10 % higher ketene polymers.

Some physical properties of diketene are listed below [1–7]:

mp	− 7.5 °C
bp	
101.3 kPa	127 °C
13.3 kPa	69 – 71 °C
5.5 kPa	50.5 °C
3.1 kPa	38.5 °C
Vapor pressure (20 °C)	1.07 kPa
d_4^{20}	1.09471
d_4^{25}	1.088754
Vapor density (20 °C, theoretical, air = 1)	2.9
n_D^{20}	1.4379
Surface tension, mN/m	
20 °C	31.82
24 °C	30.37
25 °C	33.89
Critical pressure	5.47 MPa
Critical temperature	310 °C (583.16 K)
Viscosity	0.88 mPa · s
Flash point (open cup)	33 °C
Ignition temperature (air)	291 °C
Explosive limits in air, vol%	
lower	2 ∗
upper	11.7
Dipole moment	3.53 D
Dielectric constant	16 – 17
Standard enthalpy of formation ΔG_f^0	− 233.41 J

∗ A value of 0.2 % has also been reported [55].

Diketene is miscible with acetic anhydride, with many ketones and esters (e.g., acetone, methyl acetate, ethyl acetate, butyl acetate) with diethyl ether, tetrahydrofuran, chlorinated hydrocarbons, acetonitrile, and toluene.

Furthermore, contrary to most literature reports, it is slightly soluble in aliphatic hydrocarbons such as hexane (ca. 12.5 wt % at 23 °C), octane, cyclohexane, and methylcyclohexane. It is very slightly soluble in water, in which it decomposes slowly.

3.2. Chemical Properties

Ketene itself forms primarily the unsymmetrical lactone dimer with less than 5 % being converted to the symmetrical dimer, 1,3-cyclobutanedione [*15506-53-3*], which in turn is converted to the ketene trimer [*38425-52-4*] by enol acetylation [56]. This trimer can be used to synthesize the dye intermediate squaric acid [57].

Diketene is a reactive, versatile compound, which cannot be stored indefinitely, even in the presence of stabilizing agents such as sulfates, borates, or sulfur [58]. On standing for several days or weeks, it turns yellow and then brown. Glass vessels are not recommended for storage because the basicity of glass promotes decomposition: stainless steel or aluminum is preferred.

Diketene reactions proceed mainly by ring opening and are highly exothermic. Traces of base or strong acid can lead to violent, almost explosive polymerization, and due care should be exercised when handling diketene.

Only the most important types of the large number of reactions of diketene are briefly discussed here. More detailed information can be found in [1–7], [12], [59].

Pyrolysis. Diketene is cleaved to two molecules of ketene by pyrolysis at 350 – 600 °C [34], and it is a convenient laboratory source of ketene (see Section 2.3). In a copper reactor at 550 °C and with admixture of nitrogen, decomposition can lead to allene and carbon dioxide [60].

Reactions at the Olefinic Double Bond (without Ring Opening) [61–63]. Hydrogen adds catalytically to the exocyclic olefinic double bond of diketene to form β-butyrolactone (4-methyl-2-oxetanone). This hydrogenation can be made enantioselective by using a chiral catalyst [64]. Other reactions include radical addition (e.g., with halogenated compounds, secondary alcohols, alkylthiols, dialkyl phosphites) to give 4-substituted oxetanones. Diketene can also undergo addition of carbenes and nitrenes, and photochemical [2 + 2] and thermal [4 + 2] cycloadditions with olefins and other unsaturated compounds (Diels – Alder) to give spirocyclic compounds.

Polymerization of diketene under free-radical conditions leads to a polymeric form with intact β-lactone rings. Ozonolysis to give the highly unstable malonic anhydride has been reported [65], [66].

Ring-Opening Reactions. In most reactions, the strained β-lactone ring is opened, and diketene appears to react as acetylketene or one of its tautomeric forms:

Nucleophiles normally add to the acyl carbon – oxygen bond leading to acetoacetylation:

Nu = nucleophile

A variety of compounds with active hydrogen atoms react in this manner, e.g., alcohols, phenols, carboxylic acids, hydrogen halides, amines, carboxylic acids, amides, ureas, *N*-arylhydroxylamines, and sulfonamides. With the less reactive compounds, a catalyst is often required. When other functional groups are present (e.g., ureas, thioureas, hydrazines, hydroxylamines, amidines, urethanes, enamines, and amides), acetoacetylation can be followed by ring closure with either the keto group or the active methylene group of the acetoacetyl moiety. This leads to a variety of heterocyclic compounds [67], an example is:

Water hydrolyzes diketene only very slowly, leading to the unstable acetoacetic acid, which further decomposes to acetone and carbon dioxide [68].

Electrophiles react first with the exocyclic olefinic double bond of diketene. Subsequent nucleophilic attack at the lactone carbonyl group gives 4-substituted acetoacetic acid derivatives. Thus, chlorine gives the versatile building block 4-chloroacetoacetyl chloride [69]. Bromine reacts analogously, and reaction with fluorine at − 78 °C gives the corresponding 4-fluoro derivatives [70].

With *carbonyl compounds,* diketene gives 2,2-disubstituted 6-methyl-4*H*-1,3-dioxazin-4-ones (**6**):

6

The use of specific Ti-catalysts produces chiral 4–alkyl-3–hydroxybutanoates [71]. The most common adduct, diketene – acetone (**6**, R = CH_3), 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one, is often used as a convenient diketene replacement, because it reacts similarly to diketene, but is safer to handle and to transport [72], [73].

Analogously, compounds with C = N groups, such as carbodiimides and imines, lead to 1,3-oxazines:

Diketene Polymers. Under various conditions, diketene dimerizes to give dehydroacetic acid [74]. This compound is frequently encountered as a byproduct in reactions of ketene and diketene.

Dehydroacetic acid

With $HgCl_2$, ion-exchange resins, or alkoxides, a low molecular mass polyester of the form **1** (Section 3.1) is obtained. With BF_3 the formation of a polyketone of repeating $-(CH_2-CO-)$ units **2** has been reported [75], [76]. With vinyl monomers, diketene affords copolymers with useful properties for adhesives, unsupported films, and molded objects [77].

3.3. Production

Ketene possesses a considerable tendency to polymerize. Under controlled conditions and in the appropriate dimerization medium, ketene can be dimerized to diketene, with yields of up to 85 %, based on acetic acid (see also Section 2.2). The remaining 15 % is made up by higher ketene oligomers [56]. The preferred dimerization medium is diketene itself [78]. Crude diketene, containing 3 – 4 % acetic anhydride, is a mobile, dark brown liquid due to 8 – 10 % higher polymers. Diketene of > 99.5 % purity can be obtained by distillation [79]. Ultrapure diketene (99.99 %) can be obtained by crystallization [80].

Diketene is now generally consumed at the site of production, because of its extreme reactivity and hazardous properties. In many cases, the 1 : 1 adduct of diketene and acetone, 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one [*5394-63-8*] (**6**, R = CH_3) can be used in place of diketene [72].

3.4. Storage, Handling, and Transportation

Pure diketene is surprisingly stable at temperatures up to ambient in the absence of acid or base catalysts. Liquid diketene is stable for several weeks at 0 °C, slow polymerization occurs above 15 °C. At elevated temperature, diketene undergoes slow decomposition and discoloration. Diketene can be stabilized with agents such as water [81], sulfur [82], alcohols, phenols, borate, and sulfate salts. In Japan, lactic acid is reportedly used. Diketene, stabilized with 1 % anhydrous copper sulfate, retains its strength for up to one year at 25 °C.

Nevertheless, due to the high reactivity of diketene and transportation restrictions in certain countries, diketene is mainly used at the site of production. Hazard classifications for transportation follow:

IMDG code: class 3.3
RID/ADR: class 3, no. 31 c
CFR 49: 172.101 flammable liquid
UN number: 2521

In the United States and Japan, diketene is shipped in refrigerated tank trucks. Care must be taken to keep shipping time to a minimum and to ensure that the diketene is used upon arrival. Due to the potential hazard of shipping diketene, however, this practice is being discontinued in the United States.

Most reactions with diketene are strongly exothermic; it is therefore generally added in a small stream or in portions to other reactants. A build-up of unconverted diketene is thereby avoided. Diketene should not be stored in glass bottles due to the alkalinity of glass; stainless steel or aluminum containers should be used.

The total annual worldwide production of diketene is estimated at ca. 130 000 t. The major producers are Lonza, Eastman Chemical, Clariant, Wacker, Daicel, and BASF [14].

3.5. Uses

Diketene is a powerful bactericidal agent [83] and can raise the octane rating of gasoline [84],

but is not used for these purposes in the Western hemisphere.

The main reactions and uses of diketene have been comprehensively reviewed [7], [12], [59]. The most important industrial uses and some newer developments are highlighted in the following sections.

3.5.1. First-Generation Diketene Derivatives

First- and second-generation diketene derivatives are depicted in Figure 1.

Acetoacetates. In the presence of tertiary amine catalysts, diketene reacts rapidly with lower alcohols. Industrially preferred catalysts include trimethylamine [*75-50-3*], triethylamine [*121-44-8*], and pyridine [*110-86-1*] [85]. Acidic catalysts such as sulfuric and sulfonic acids can also be used [86], [87]. The industrial acetoacetylation of alcohols is carried out continuously in a loop reactor at 50 – 80 °C without solvent. A comprehensive treatment of acetoacetate chemistry is given in [12], [88]. Methyl and ethyl acetoacetates [*141-97-9*] are the most widely used esters, finding use in the pharmaceutical, agricultural, and allied industries.

2-Chloro- and 4-Chloroacetoacetates. The most specific chlorinating agent for acetoacetates in the 2-position is sulfurylchloride. Alternatively, diketene can be treated with hydrogen chloride at low temperature in chlorinated hydrocarbon solvents to afford acetoacetyl chloride [89], which is then chlorinated in the 2-position in excellent yield to give 2-chloroacetoacetyl chloride. The latter can be further treated with alcohols or with aliphatic or aromatic amines to afford the corresponding 2-chloroacetoacetate derivatives [90].

4-Chloroacetoacetates are conveniently prepared on an industrial scale by reaction of gaseous chlorine with diketene to form 4-chloroacetoacetyl chloride [91], which can react further with chlorine to afford 2,4-dichloroacetoacetyl chloride. Subsequent reaction with alcohols gives the corresponding 2,4-dichloroacetoacetates [92].

4-Chloroacetoacetates can be converted to the corresponding 4-alkoxyacetoacetates [93], useful starting materials for tetronic acid [94], [95]. Treatment of 2-chloro- and 2,4-dichloroacetoacetyl chlorides with water in the cold affords chloroacetone and 1,3-dichloroacetone, respectively [96].

6-Methyluracil [*626-48-2*] is produced by condensation of diketene with urea. It is used in the production of the analgesic mepirizole, the feed additive orotic acid, and 5-aminoorotic acid.

Diketene – acetone adduct [*5394-63-8*] can be regarded as a stabilized form of diketene. It can be safely transported and may conveniently be used instead of diketene in many reactions. For example, it reacts with alcohols and amines to yield acetoacetates and acetoacetamides, respectively.

Diketene – acetone adduct generates unstable acetylketene together with acetone when heated above 120 °C [97]. Subsequent condensation with isocyanates, arylcyanates, or substituted cyanamides gives access to a wide range of 1,3-oxazine derivatives [98]. Furthermore, diketene – acetone adduct can also be used for the preparation of a variety of compounds that are not accessible from diketene [72].

Dehydroacetic Acid. Controlled dimerization of diketene in the presence of tertiary amine catalysts produces dehydroacetic acid [*771-03-9*], DHA, 3-acetyl-4-hydroxy-6-methyl-2-pyrone [99]. Many other bases are also useful dimerization catalysts, e.g., sodium acetate, potassium sorbate, and sodium alkoxides or sodium phenoxides.

On standing at room temperature, diketene is slowly converted to DHA, which is frequently observed as a byproduct in reactions of diketene. In most cases, DHA can be easily removed from

Figure 1. Diketene derivatives of the first generation (inner segments) and second generation (outer segments)

the reaction mixture by bicarbonate extraction or by precipitation.

Dehydroacetic acid or its sodium salt is used as a food and cosmetic preservative, as a starting material for the veterinary drug clopidol [*2971-90-6*] (Coyden), and in the production of 4-hydroxy-6-methyl-2-pyrone.

Acetoacetalkylamides and Acetoacetarylamides. Aqueous ammonia and alkylamines react readily with diketene to form acetoacetamide and acetoacetalkylamides, respectively, whereas arylamines react more slowly to afford acetoacetanilides. Arylhydrazines yield 3-methyl-1-aryl-5-pyrazolones. Sulfamic acid reacts to give, after cyclization, the sweetener Acesulfame [100].

Acetoacetamide and acetoacetalkylamides are mainly used as aqueous solutions. The main uses for the alkylamides are in the production of insecticides such as monocrotophos, dicrotophos, phosphamidon, and oxamyl. *N*-(2-Hydroxyethyl)-3-oxobutanamide [*24309-97-5*] is used in the production of olaquindox, a growth stimulant for pigs.

Acetoacetarylamides are mainly used in the production of high-quality organic pigments, particularly as azo coupling components, e.g., for a variety of yellow and orange pigments. The simplest compound of this series, acetoacetanilide [*102-01-2*], is also used in the production of the fungicides carboxin and methfuroxam, in addition to its use in the production of the pigment yellow 12.

β-Butyrolactone. Diketene undergoes catalytic hydrogenation to give β-butyrolactone, 4-methyl-2-oxetanone [*3068-88-0*] in ethyl acetate at 0 °C over a palladium catalyst [102]. β-Butyrolactone is used in the production of the analgesic bucetin. Enantioselective reduction to chiral β-butyrolactone has been reported [64].

3.5.2. Second-Generation Diketene Derivatives

A number of second-generation diketene derivatives (see Fig. 1) have already been mentioned in Section 3.5.1. A few are selectively described here.

3-Aminocrotonate esters, e.g., methyl 3-aminocrotonate [*14205-39-1*] (3-amino-2-butenoic acid, methyl ester) can be prepared by treatment of acetoacetates with aqueous ammonia [103]. They are mainly used in the production of a series of the dihydropyridine-type calcium antagonists.

2-Aminothiazol-4-yl Acetates. Diketene can be used in a number of ways for the preparation of substituted acetoacetamido side chains for β-lactam antibiotics, e.g., by conversion of the 4-chloroacetoacetamido side chain of 4-chloroacetoacetamidocephalosporanic acid with thiourea [104]. Alternatively, the aminothiazolylacetic acid side chains can be prepared separately for attachment to a variety of β-lactams [105] (e.g., semisynthetic cephalosporins of the third and fourth generation and of carbapenems [106]).

Acetoacetoxyethyl methacrylate [*21282-97-3*], AAEM, has a pendant acetoacetoxyethyl group which can modify the physical properties of acrylic polymers by decreasing solution viscosity and lowering the glass transition temperature. In addition, the acetoacetyl group contains an active methylene group and a carbonyl group, which can be used to modify or cross-link the polymer [107].

4. Higher Ketenes

4.1. Properties

Higher ketenes are divided into aldoketenes RCH=C=O and ketoketenes $R^1R^2C{=}C{=}O$ depending on whether one or two hydrogen atoms of ketene are substituted by an alkyl or aryl group. They are less important industrially than ketene or diketene.

Physical Properties. Methylketene is a gas at room temperature; most other aldo- and ketoketenes are yellow to reddish-brown liquids, some higher diarylketenes are solids. Some physical properties of the most common aldo- and ketoketenes are given in Table 1.

Chemical Properties. The chemical behavior of the higher ketenes is essentially the same as that of ketene [1] although there are some noticeable differences. Aldoketenes are extremely reactive, and it is very difficult to isolate the monomeric form. They are, therefore, generated and used in situ [1], [2], [9], [11].

Ketoketenes differ from ketene and aldoketenes in one important respect: they are oxidized by molecular oxygen even at temperatures well below 0 °C (− 80 °C has been reported for some aryl ketenes), forming hazardous peroxides that can explode at the slightest touch. Ketoketenes must therefore only be handled under an oxygen-free atmosphere. In all other reactions, including polymerization, ketoketenes are less reactive than aldoketenes or ketene itself: more forcing reaction conditions or a catalyst are often required. Ketoketenes, particularly diarylketenes, can be stored in oxygen- and catalyst-free solutions for longer periods, up to several months, due to their lower reactivity. Small amounts of aluminum trialkyl can be added to prevent peroxide formation [31].

4.2. Production and Uses

Various methods are available for the production of higher ketenes; the method used depends on the ketene [11], [108].

Dialkylmalonic acids are useful starting materials for the preparation of dialkylketenes. When dimethylmalonic acid is heated with

Table 1. Physical properties of higher ketenes

Name	CAS registry number	M_r	*bp* °C (kPa)	n_D^{20}
Methylketene	[*6004-44-0*]	56.06	− 56 (101.3)	
Ethylketene	[*20334-52-5*]	70.09	36 (101.3)	
Phenylketene	[*3496-32-0*]	118.14		
Dimethylketene	[*598-26-5*]	70.09	34 (101.3) (*mp* 98 °C)	
Methylethylketene	[*36854-53-2*]	84.12	− 26 (1.60)	
Diethylketene	[*24264-08-2*]	98.15	91 (101.3)	1.4126
Di-*n*-propylketene	[*58844-38-5*]	126.20	30 (1.47)	
Di-*n*-butylketene	[*36638-69-4*]	154.25	68 (1.40)	1.4308
Di-*tert*-butylketene	[*19824-34-1*]	154.25	73 (6.0)	1.4370
Methylphenylketene	[*3156-07-8*]	132.16	74 (1.6) (*mp* − 8 to − 5 °C)	
Ethylphenylketene	[*20452-67-9*]	146.19	42 (0.04)	
Diphenylketene	[*525-06-4*]	194.23	119 (0.47) (*mp* 9 – 10 °C)	1.615

acetic anhydride, the intermediate cyclic acylal of dimethylketene and dimethylmalonic acid [*595-46-0*] can be isolated [109]. This compound gives dimethylketene on pyrolysis at 130 °C.

Diphenylketene is made by removal of hydrogen chloride from diphenylacetyl chloride with triethylamine [110]. This method is generally useful for the in situ preparation of ketenes, whereby the transient ketene can be captured by a ketenophile [9], [11], [111].

Long-chain monoalkylketenes (aldoketenes) and their lactone dimers, the alkylketene dimers, have been used for paper sizing for many years. They are prepared by removal of hydrogen chloride from long-chain fatty acid chlorides, e.g., stearic acid chloride. The intermediate highly reactive ketene dimerizes to the lactone dimer (*mp* ca. 50 °C) in the presence of acidic catalysts [112]:

Emulsions of these sizing agents (so-called AKD's) form covalent bonds with the hydroxyl groups of cellulose below 100 °C, making fiber surfaces hydrophobic [113–115].

5. Toxicology and Occupational Health

Ketene is one of the most irritating gases to the respiratory tract, due to its great reactivity towards nucleophiles such as hydroxyl, amino, carboxyl, thiol, and phenolic groups, leading to acetylation of proteins. Its toxicity is considered to be of the same order of magnitude as that of phosgene [117]. Like the latter, it also causes latent damage to the respiratory tract (pulmonary edema) that may become acute only many hours after exposure.

Different, sometimes conflicting values, are found in the literature for inhalation toxicity [54], [117–119]. This could indicate a different sensitivity in different species, but is more likely to be due to the instability of ketene, which makes it difficult to maintain and measure a low concentration over a long time. The LCLo (mouse) is 23 ppm (30 min), 53 ppm (100 min) in the rat, rabbit, and guinea pig and 200 ppm (10 min) in the monkey; other sources report an LC_{100} of 200 ppm (5 min) in the rat. No toxic effects were reported with a concentration of 1 ppm for 7 h/d during 55 days. No human casualties have been reported, although irritation of the respiratory tract and of the eye due to unknown concentrations of ketene among workers is known. After inhalation of even small quan-

tities, a characteristic, long-lasting, unpleasant taste can be observed; smokers seem to be more sensitive to this phenomenon.

The LD_{50} of ketene (rat, oral) is 1300 mg/kg [119].

The TLV-TWA exposure limit for ketene is 0.5 ppm (0.9 mg/m^3), which is also the MAK value in the Federal Republic of Germany and in Switzerland. Regarding the maximal allowable instantaneous concentration, the TLV-STEL value is 1.5 ppm; the German MAK commission classifies ketene in category I with a limit twice the MAK (corresponding to 1 ppm) which is to be tolerated for no longer than 5 min, and no more than eight times a day [119–122]. No carcinogenic activity for ketene has been reported.

Diketene [117–119], [122], [123]. Although less acutely toxic than ketene, diketene is a strongly irritating agent and a powerful lachrimator. It is especially dangerous to the eye (in which it rapidly damages the corneal tissue) and to the respiratory tract; formation of pulmonary edema is possible for up to two days after exposure.

Symptoms of diketene exposure are a burning sensation in the eyes, nose, and throat, coughing, difficulty in respiration and ultimately loss of consciousness. A physician should be consulted immediately after inhalation of the vapor. Liquid diketene can be absorbed through the skin, where it causes itching and burning. No chronic toxic effects are known.

The acute oral toxicity (LD_{50}) is 560 mg/kg (rat) and 800 mg/kg (mouse). The reported LCLo is 20 000 ppm for an exposure of 1 h. The acute dermal toxicity LD_{50} in the rabbit has been given as 2.83 mL/kg and 6730 mg/kg.

No carcinogenic effects of diketene have been found on skin application in mice or subcutaneous injection and intragastric feeding in rats [124–126].

No permissible exposure limits have been set. Diketene has a pronounced "warning" effect due to its very low irritation threshold, and, when inhaled, it becomes unbearable before a lethal limit is reached.

Higher Ketenes. No toxicological data have been reported for higher ketenes, but it is prudent to consider them at least as hazardous and toxic as ketene itself.

1. Introduction

Ketones are organic compounds that contain a carbonyl group and two aliphatic or aromatic substituents.

The substituents R^1 and R^2 may be saturated or unsaturated, linear or branched alkyl groups, or aromatic residues. They may be the same or different. Moreover, the alkyl or aryl substituents can also contain heteroatoms. More than one carbonyl group may be present in a particular molecule.

Chemical Properties. The alkyl and aryl groups of ketones act as electron donating groups toward the carbon atom of the carbonyl group. As a result, the reactivity of the carbonyl group is lower than that of, for example, aldehydes. This is also clear from a consideration of the limiting electronic structures with which ketones can be described:

In addition, the reactivity of the carbonyl group is influenced considerably by steric effects, e.g., branching at the α-carbon atom.

Industrially, the most important reactions of ketones are hydrogenation, reductive condensation, reductive amination, oxidation to peroxides, ketal formation, and condensation reactions. The acidic character of the α-hydrogen atoms flanking the carbonyl group enables numerous substitution and addition reactions to take place, e.g., the aldol reaction.

A typical property of ketones is the ability to enolize, this is particularly important for β-diketones (see next page).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_077

The carbon atom of the carbonyl group is sp^2 hybridized and so the substituents lie in the plane of the carbonyl group. Ketones are therefore prochiral, and enantioselective reactions at the carbonyl group can lead to chiral compounds.

Physical Properties. Aliphatic and cyclic ketones with ten carbon atoms or less are largely stable, colorless liquids that have a pleasant odor. They are miscible with organic solvents and are good solvents for paints, cellulose ethers, nitrocellulose, etc. Some are used as flavors and fragrances (→ Flavors and Fragrances).

Production. As a result of the high stability of ketones, they can be synthesized in a multitude of ways, however only a few processes are practised industrially. Reactions such as condensation of methyl alkyl ketones with compounds containing acidic C−H groups or the ketonization of carboxylic acids or aldehydes are important. The functionalization of an existing carbon skeleton (e.g., by oxidation of alcohols, olefins, or alkanes) plays an important role.

Economic Aspects. Although solvent-poor or solvent-free systems have been developed and solvent recycling is becoming more widespread, ketones have retained their economic importance because they are increasingly replacing other solvents (e.g., chlorinated hydrocarbons) for aromatic compounds.

2. Methyl Alkyl Ketones

For acetone, see → Acetone. For 2-butanone (methyl ethyl ketone), see → 2-Butanone.

2.1. 3-Methyl-2-butanone

3-Methyl-2-butanone [*563-80-4*], methyl isopropyl ketone, $CH_3COCH(CH_3)_2$, $C_5H_{10}O$, M_r 86.13.

Properties. 3-Methyl-2-butanone is a colorless liquid with a characteristic ketone odor. Some physical properties are listed below:

mp	−92 °C
bp	94–95 °C
d_4^{20}	0.803
n_D^{20}	1.3890
Flash point	6 °C
Solubility in water (20 °C)	6.52 wt %

3-Methyl-2-butanone undergoes condensation reactions preferentially at the methyl group. The tertiary carbon atom is easily oxidized and the resulting hydroperoxide (*mp* 26–27 °C) can be produced by base-catalyzed air oxidation [1].

The use of condensation reactions of the methyl group and reactions of the carbonyl group for synthesis have been described.

Production. 3-Methyl-2-butanone is produced industrially by the following reactions:

1) Condensation of 2-butanone [*78-93-3*], formaldehyde, and hydrogen in a single step over palladium [2], or in two steps by condensation on a strongly acidic cation exchanger, isolation of the 2-methyl-1-buten-3-one, followed by hydrogenation [3]:

2) By reaction of isobutyraldehyde with acetaldehyde in the gas phase over manganese oxide – aluminum oxide at 450 °C [4]:

Isobutyric acid and acetic acid may be used in place of isobutyraldehyde and acetaldehyde [5].

3) By addition of water to isoprene at ca. 200 °C in the presence of phosphoric acid on silica [6]:

4) By oxidation of 2-methyl-2-butene with oxygen [7] or hydroperoxides in the presence of molybdenum naphthenate at 150 °C [8]:

Storage and Transportation. 3-Methyl-2-butanone is available with a purity of > 98 wt %. The following regulations apply to storage and transportation. Labelling according to the Gefahrstoffverordnung (GefStoffV, Federal Republic of Germany) [9]: F; R phrase: 11; S phrases: 9 – 16 – 33. Hazard codes for transportation are as follows [10–12]:

IMDG Code: class 3.2
RID/ADR: class 3, number 36
CFR 49: 172.102 flammable liquid
VbF: A 1
UN number: 2397
EEC number: 5788

Containers of V2A steel are used for transportation and storage.

Uses. 3-Methyl-2-butanone is employed predominantly as an intermediate for the production of pharmaceuticals, herbicides [13], and dye precursors [14]. It is also used in the synthesis of rubber auxiliaries and for the selective extraction of rare earth elements [15].

2.2. 4-Methyl-2-pentanone

4-Methyl-2-pentanone [*108-10-1*], methyl isobutyl ketone, MIBK, $CH_3COCH_2CH(CH_3)_2$, $C_6H_{12}O$, M_r 100.16.

Properties. 4-Methyl-2-pentanone is a colorless liquid with a less pronounced ketone-like odor. Some physical properties are given below:

mp	– 80 °C
bp	116 °C
d_4^{20}	0.8004
n_D^{20}	1.3959
Enthalpy of evaporation	36.15 kJ/mol
Specific heat (20 °C)	1922 kJ/g
Enthalpy of combustion	3740 kJ/mol
Flash point (DIN 51 755)	14 °C
Ignition temperature	475 °C
Ignition class (VED)	G1
Explosion class (VED)	1
Solubility at 25 °C	
4-Methyl-2-pentanone in water	1.7 wt %
Water in 4-methyl-2-pentanone	1.9 wt %

4-Methyl-2-pentanone is poorly soluble in water but is miscible with common organic solvents. It forms an azeotrope with water and with a large number of solvents. For example, the azeotrope with water (*bp* 87.9 °C) contains 75.7 wt % 4-methyl-2-pentanone, and that with *n*-butanol (*bp* 114.4 °C) 70 wt % 4-methyl-2-pentanone.

4-Methyl-2-pentanone undergoes autoxidation to form a peroxide:

After evaporation of 4-methyl-2-pentanone – water mixtures in the presence of air, a dangerous, increasing concentration of peroxide in the aqueous phase has been reported [16]. The peroxide can also be obtained directly by oxidation with 50 % hydrogen peroxide in the presence of acids [17].

In condensation reactions with carbonyl compounds such as acetone, the α-methyl group usually reacts. Only formaldehyde is able to undergo condensation reactions with the α-methylene group [18]. The usual industrial reactions such as hydrogenation and reductive amination may be carried out with the keto group.

Production. 4-Methyl-2-pentanone can be produced industrially from acetone or isopropyl alcohol according to the following four processes:

1) In three steps from acetone via diacetone alcohol and mesityl oxide, with subsequent hydrogenation.
2) In two steps from acetone via mesityl oxide.
3) In one step from acetone and hydrogen.
4) As a byproduct in the dehydrogenation of isopropyl alcohol to acetone.

In the *three-step process* acetone undergoes alkali-catalyzed condensation in the first step to form diacetone alcohol. Dehydration of the latter to mesityl oxide takes place in the liquid phase at 90 – 130 °C over an acid catalyst, such as phosphoric or sulfuric acid, with high selectivity [19]. Selective hydrogenation of the carbon – carbon double bond in mesityl oxide to give 4-methyl-2-pentanone may be carried out in both the liquid phase and the gas phase with various catalysts, preferably palladium [20]. The selectivity is excellent.

Dehydration and hydrogenation can also be combined into a single process step.

The *two-step process* is less important industrially. Acetone is converted in a single step to mesityl oxide, which is then hydrogenated to 4-methyl-2-pentanone in a second step. Catalysts such as copper chromite [21] or zirconium phosphate [22] are used for the condensation, and palladium on aluminum oxide for the hydrogenation. 4-Methyl-2-pentanol [*108-11-2*] is formed as a byproduct.

For the *single-step production* of 4-methyl-2-pentanone from acetone and hydrogen a combination of a cation exchanger with palladium is generally used as catalyst [23]. The acetone is fed with hydrogen over the palladium-charged catalyst at 130 °C and 0.5 – 5.0 MPa. A selectivity of > 95 % at a conversion of < 50 % is thereby attained. As a result of the increasing production of acetone by dehydrogenation of isopropyl alcohol, the production of 4-methyl-2-pentanone as a byproduct in this process is becoming more important [24] (see also → Acetone, Chap. 4.2.).

Storage and Transportation. 4-Methyl-2-pentanone is available with a purity of > 99 %. Typical specifications are given below:

Content	> 99 wt %
Water content (ASTM D 1364)	0.1 % max.
Hazen color no. (APHA, DIN 53 409)	10 max.
Nonvolatile residue (ASTM D 1353)	0.002 wt % max.
Boiling range (DIN 51 751)	114 – 117 °C
Acid content (as acetic acid)	0.002 wt % max.

Conditions that could lead to autoxidation (presence of air, light, heat, or heavy metals) or condensation (strongly acidic or basic media) should be avoided during storage. Containers of V2A steel are recommended for both storage and transportation.

Transportation is governed by the following regulations: Labelling according to GefStoffV [9]: F; R phrase: 11; S phrases: 9 – 16 – 23 – 33. Hazard codes for transportation are as follows [10]:

IMDG Code: class 3.2
RID/ADR: class 3, number 3 b
CFR 49: 172.101 flammable liquid
UN number: 1245

Uses. The major application of 4-methyl-2-pentanone is as a solvent for vinyl, epoxy, and acrylic resins, for natural resins, and for nitrocellulose. A further use is as a solvent for dyes in the printing industry. 4-Methyl-2-pentanone is also a versatile extracting agent, e.g., for the production of antibiotics, or the removal of paraffins from mineral oil for the production of lubricating oils. The importance of 4-methyl-2-pentanone as an intermediate for synthesis is relatively low. The most important product is 4-methyl-2-pentanol, obtained by hydrogenation of the ketone. 4-Methyl-2-pentanone peroxide has some importance as a polymerization initiator for ethylene [25] and for the hardening of unsaturated polyester resins [26].

Economic Aspects. In terms of production volume, 4-methyl-2-pentanone lies behind acetone and 2-butanone as the most important aliphatic ketone. In 1987 production in Europe was 70 000 t, in the United States 70 000 t, and in Japan 40 000 t. The total produced amounted to 180 000 t. In 1996 production in Western Europe was 100 000 t, in Japan 60 000 t, and in the Federal Republic of Germany 18 000 t. The total produced amounted to 380 000 t [118].

2.3. 3-Methyl-2-pentanone

3-Methyl-2-pentanone [*565-61-7*], methyl *sec*-butyl ketone, $CH_3COCH(CH_3)CH_2CH_3$, $C_6H_{12}O$, M_r 100.16.

Properties. 3-Methyl-2-pentanone is a colorless liquid with an odor reminiscent of peppermint. Some physical properties are listed below:

mp	− 83 °C
bp	116 °C
d_4^{20}	0.8130
n_D^{20}	1.4012
Flash point	12 °C
Solubility in water (20 °C)	2.26 wt %

Production. 2-Butanone undergoes base-catalyzed aldolization with acetaldehyde to form 4-hydroxy-3-methylpentan-2-one [27]. Acid-catalyzed dehydration to 3-methyl-3-penten-2-one [28] is followed by hydrogenation over a palladium catalyst to give 3-methyl-2-pentanone:

Uses. 3-Methyl-2-pentanone is used as a solvent. Its use as an intermediate for various syntheses has been reported, but the industrial importance is relatively low [29].

2.4. 3,3-Dimethyl-2-butanone

3,3-Dimethyl-2-butanone [*75-97-8*], *tert*-butyl methyl ketone, pinacolone, $CH_3COC(CH_3)_3$, $C_6H_{12}O$, M_r 100.16.

Properties. 3,3-Dimethyl-2-butanone is a colorless liquid with a light peppermint- or camphor-like odor.

mp	− 52.5 °C
bp	106.2 °C
d_4^{20}	0.801
n_D^{20}	1.3964
Flash point	23 °C
Solubility in water (15 °C)	2.44 wt %

3,3-Dimethyl-2-butanone is stable toward autoxidation; under standard conditions it does not form hydroperoxides.

Only the α-methyl group can undergo condensation reactions. At the carbonyl group the usual reactions (hydrogenation, reductive amination) can take place.

Production. 3,3-Dimethyl-2-butanone can be produced by the following routes:

Hydrolysis of 4,4,5-trimethyl-1,3-dioxane, the product of the Prins reaction of isoprene with formaldehyde [30]

The reductive dimerization of acetone under the influence of an acid catalyst with simultaneous rearrangement (the pinacol rearrangement) [31]

Ketonization of pivalic acid with acetic acid or acetone over thorium, zirconium, or cerium catalysts [32]

Oxidation of 2,3-dimethyl-2-butene with hydrogen peroxide [33]:

Uses. 3,3-Dimethyl-2-butanone is produced in large amounts for fungicides, e.g., Triademefon (Bayer) [34]. An important intermediate for this type of fungicide is triazolylpinacolone [*58905-32-1*]. A further use is the synthesis of herbicides, e.g., Metribuzin (Bayer) [35].

2.5. 2-Heptanone

2-Heptanone [*110-43-0*], methyl pentyl ketone, methyl amyl ketone,$CH_3COCH_2(CH_2)_3CH_3$, $C_7H_{14}O$, M_r 114.18.

Properties. 2-Heptanone is a colorless liquid with a fruity odor.

mp	−35 °C
bp	149–150 °C
d_4^{20}	0.820
n_D^{20}	1.4085
Flash point	47 °C

Production. 2-Heptanone is produced industrially by reductive condensation of acetone with butyraldehyde in one or two steps [36]:

Storage and Transportation. Labelling according to GefStoffV (class II d) [9]: X_n; R phrases: 10–22; S phrase: 23. Hazard classifications are as follows:

IMDG Code: class 3.3
RID/ADR: class 3, number 31 c [10]
CFR 49: 172.101/102 flammable liquid
UN number: 1110

Uses. 2-Heptanone is used as a solvent and as a synthetic building block.

2.6. 5-Methyl-2-hexanone

5-Methyl-2-hexanone [*110-12-3*], methyl isoamyl ketone, $CH_3COCH_2CH_2CH(CH_3)_2$, $C_7H_{14}O$, M_r 114.18.

Properties. 5-Methyl-2-hexanone is a colorless liquid with an odor similar to that of amyl acetate.

mp	−41 °C
bp	145 °C
d_4^{20}	0.888
n_D^{20}	1.4062
Flash point	41 °C

Production. 5-Methyl-2-hexanone is produced by condensation of acetone with isobutyraldehyde [37]. This reaction may be carried out in one or two steps, in the liquid or in the gas phase [38]:

Storage and Transportation. Labelling according to GefStoffV [9]: R phrase: 10; S phrase: 23. Hazard codes for transportation are as follows:

IMDG Code: class 3.3
RID/ADR: class 3, number 31 c
CFR 49: 172.102 flammable liquid
UN number: 2302

Uses. 5-Methyl-2-hexanone is used as a solvent for the production of high-solids coatings, because it possesses a high solubility for alkyd resins, acrylic resins, cellulose esters, cellulose nitrate, and vinylic copolymers.

2.7. 2-Octanone

2-Octanone [*111-13-7*], methyl hexyl ketone, $CH_3COCH_2(CH_2)_4CH_3$, $C_8H_{16}O$, M_r 128.21.

Properties. 2-Octanone is a colorless liquid with an odor reminiscent of apples and a taste similar to that of camphor.

mp	−16 °C
bp	173 °C
d_4^{20}	0.819
n_D^{20}	1.4150
Flash point	62 °C

Production. 2-Octanone is produced industrially by two methods:

1) Reductive condensation of acetone with pentanal [39]:

$$CH_3-\underset{\underset{O}{\|}}{C}-CH_3 + OHCCH_2CH_2CH_2CH_3 \xrightarrow{H_2,\ Cat.} CH_3-\underset{\underset{O}{\|}}{C}-CH_2(CH_2)_4CH_3 + H_2O$$

2) Oxidation of 1-octene with hydrogen peroxide in the presence of a catalyst containing rhenium oxide or a special palladium–copper catalyst in the presence of nitriles [40]:

$$CH_2=CH(CH_2)_5CH_3 \xrightarrow{H_2O_2,\ Cat.} CH_3-\underset{\underset{O}{\|}}{C}-CH_2(CH_2)_4CH_3$$

Uses. 2-Octanone is used as an intermediate and in fragrance compositions.

2.8. Higher Methyl Alkyl Ketones

Properties. The higher straight-chain methyl alkyl ketones (C_9–C_{18}) are colorless liquids or solids, with characteristic odors. The melting point of methyl alkyl ketones with 12 or more carbon atoms lies at room temperature or above. The most important physical properties are listed in Table 1.

Production. Higher methyl *n*-alkyl ketones can be prepared by the following processes:

1) Catalytic gas-phase ketonization of acetic acid with fatty acids [5]:

$$CH_3COOH + RCOOH \longrightarrow CH_3COR + CO_2 + H_2O$$

2) Catalytic gas-phase condensation of acetaldehyde with an *n*-aldehyde [41], [42]:

$$CH_3CHO + RCHO \longrightarrow CH_3COR + CO + H_2$$

3) Catalytic dehydrogenation of secondary alcohols [43]:

$$CH_3-\underset{\underset{OH}{|}}{CH}-CH_2R \xrightarrow{-H_2} CH_3-\underset{\underset{O}{\|}}{C}-CH_2R$$

4) Direct catalytic oxidation of α-olefins [40], [44]:

$$CH_2=CH-CH_2R \xrightarrow[Cat.]{[O_2]} CH_3-\overset{\overset{O}{\|}}{C}-CH_2R$$

5) Oxidation of α-olefins with organic hydroperoxides in the presence of palladium complex catalysts [45]:

$$CH_2{=}CH(CH_2)_9CH_3 + (CH_3)_3COOH \longrightarrow CH_3CO(CH_2)_9CH_3 + (CH_3)_3COH$$

Uses. Higher methyl alkyl ketones are used as nonvolatile solvents for resins and rubber formulations, and also as plasticizers. Condensation products with hexahydropyrimidines [46] or 1,4-phenylenediamine [47] are used in the production of antioxidants and vulcanization accelerators.

3. Dialkyl Ketones

3.1. 3-Pentanone

3-Pentanone [*96-22-0*], diethyl ketone, $CH_3CH_2COCH_2CH_3$, $C_5H_{10}O$, M_r 86.13.

Table 1. Physical properties of higher linear methyl alkyl ketones

Total number of carbon atoms	M_r	*mp*, °C	*bp*, °C (kPa)	Flash point, °C
C_9	142.2	−8 to −9	194 (101.3)	160
C_{10}	156.3	2–3	210 (101.3)	
C_{11}	170.3	11–12	223 (101.3)	192
C_{12}	184.3	20–21	144 (14.5)	
C_{13}	198.3	27–28	120 (6.5)	225
C_{16}	240.4	43	165 (16)	
C_{17}	254.4	45–46	156 (4)	248
C_{18}	268.5	52	251–252 (133)	

Properties. 3-Pentanone is only slightly soluble in water, but miscible with organic solvents.

mp	−40 °C
bp	102 °C
d_4^{20}	0.814
n_D^{20}	1.3924
Flash point	12 °C
Ignition temperature	445 °C

Production. 3-Pentanone can be produced by catalytic ketonization of propionic acid over a thorium oxide or zirconium oxide catalyst at 350–380 °C [48]. Hydroformylation of ethylene in the presence of cobalt carbonyl complexes at 100 °C is a further route [49]:

$$2\,CH_2{=}CH_2 + CO + H_2 \xrightarrow{\text{Cat.}} CH_3CH_2{-}\underset{\underset{O}{\|}}{C}{-}CH_2CH_3$$

Storage and Transportation. The following regulations apply:Labelling according to GefStoffV [9]: F; R phrase: 11; S phrases: 9–16–33. Hazard classifications for transportation are as follows [10–12]:

IMDG Code: class 3.2
RID/ADR: class 3, number 3 b
CFR 49: 172.101 flammable liquid
VbF: A1
UN number: 1156
EEC number: 5789

Uses. 3-Pentanone is used as a solvent for paints and as a starting material for organic syntheses, e.g., for the production of trimethylphenol, a precursor of vitamin E. A further use is in fragrances.

3.2. 2,4-Dimethyl-3-pentanone

2,4-Dimethyl-3-pentanone [*565-80-0*], diisopropyl ketone, $(CH_3)_2CHCOCH(CH_3)_2$, $C_7H_{14}O$, M_r 114.19.

Properties. 2,4-Dimethyl-3-pentanone is a colorless liquid with a characteristic odor similar to that of camphor; it is insoluble in water but soluble in organic solvents.

mp	−69 °C
bp	125 °C
d_4^{20}	0.806
n_D^{20}	1.3990
Flash point	15 °C

Production. 2,4-Dimethyl-3-pentanone is preferably obtained by ketonization of isobutyric acid over a thorium oxide or zirconium oxide catalyst at 430 °C [50].

Storage and Transportation. Labelling according to GefStoffV [9]: F; R phrase: 11; S phrases: 16–23. Hazard classifications for transportation are as follows [10–12]:

RID/ADR: class 3, number 3 b
VbF: A1
EEC number: 5558

Uses. 2,4-Dimethyl-3-pentanone is used as a solvent and as an intermediate.

3.3. 2,6-Dimethyl-4-heptanone

2,6-Dimethyl-4-heptanone [*108-83-8*], diisobutyl ketone, $(CH_3)_2CHCH_2COCH_2CH(CH_3)_2$, $C_9H_{18}O$, M_r 142.24.

Properties. 2,6-Dimethyl-4-heptanone is a colorless liquid with a mild ketone-like odor.

mp	− 49 °C
bp	169 °C
d_4^{20}	0.808
n_D^{20}	1.4114
Flash point	60 °C
Solubility (20 °C)	
2,6-Dimethyl-4-heptanone in water	0.06 wt %
Water in 2,6-dimethyl-4-heptanone	0.45 wt %

Production. This ketone can be prepared by the dehydrogenative condensation of isopropyl alcohol with 4-methyl-2-pentanone as byproduct [51], [52]. A mixture of acetone and isopropyl alcohol may be used instead of the latter alone [53]. 2,6-Dimethyl-4-heptanone can also be produced by the reductive condensation of acetone with 4-methyl-2-pentanone [54]:

Storage and Transportation. Labelling according to GefStoffV [9]: X_i; R phrases: 10 – 37; S phrase: 24. Hazard classifications for transportation are as follows:

IMDG Code: class 3.3
RID/ADR: class 3, number 31 c [10]
CFR 49: 172.101 flammable liquid
UN number: 1157

Uses. 2,6-Dimethyl-4-heptanone is used mainly as a solvent for paints, dyes, and adhesives, and as an extraction agent and solvent for recrystallization of organic compounds.

3.4. 3-Heptanone

3-Heptanone [*106-35-4*], butyl ethyl ketone, $CH_3CH_2COCH_2CH_2CH_2CH_3$, $C_7H_{14}O$, M_r 114.19.

Properties. 3-Heptanone is a colorless liquid with a green odor.

mp	− 39 °C
bp	146 – 149 °C
d_4^{20}	0.818
n_D^{20}	1.4085
Flash point	41 °C

Production. 3-Heptanone is produced industrially by reductive condensation of propanal with 2-butanone [54]:

Storage and Transportation. Labelling according to GefStoffV [9]: X_n; R phrases: 10 –22; S phrase: 23. Hazard codes for transportation are as follows:

IMDG Code: class 3.3
RID/ADR: class 3, number 31 c [10]
CFR 49: 172.101 flammable liquid
UN number: 1993 (nos)

Uses. 3-Heptanone is used as a perfume and fragrance, as a solvent for cellulose resins, nitrocellulose resins, and vinyl resins, and as a synthetic building block.

3.5. 5-Methyl-3-heptanone

5-Methyl-3-heptanone [*541-85-5*], amyl ethyl ketone, $CH_3CH_2COCH_2CH(CH_3)CH_2CH_3$, $C_8H_{16}O$, M_r 128.22.

Properties. 5-Methyl-3-heptanone is a colorless liquid with low solubility in water (0.3 wt %); water is poorly soluble in the ketone (0.9 wt %). 5-Methyl-3-heptanone is highly soluble in common organic solvents.

mp	< − 70 °C
bp	157 – 162 °C
d_4^{20}	0.823
n_D^{20}	1.4142
Flash point	43 °C

Production. 5-Methyl-3-heptanone is obtained, together with 2-butanone, by the gas-phase dehydrogenation of *sec*-butyl alcohol. The industrial product generally contains ca. 4 % of the isomeric 3,4-dimethyl-2-hexanone [*19550-10-8*].

To increase the yield of 5-methyl-3-heptanone, the gas-phase hydrogenation of *sec*-butyl alcohol is carried out in the presence of noble metals on zinc oxide, thorium oxide, or titanium oxide supports [55]. Such catalysts promote the self-condensation of 2-butanone. 5-Methyl-3-heptanone is easily separated from 2-butanone by distillation because of the difference in boiling points.

5-Methyl-3-heptanone can also be obtained by base-catalyzed dimerization of 2-butanone, dehydration of the resulting 5-methyl-5-hydroxy-3-heptanone, and hydrogenation of the ensuing 5-methyl-4-hepten-3-one [56].

Storage and Transportation. Labelling according to GefStoffV [9]: X_i; R phrases: 10–36/37; S phrase: 23. Hazard codes for transportation are as follows:

IMDG Code: class 3.3
RID/ADR: class 3, number 31 c [10]
CFR 49: 172.102 flammable liquid
UN number: 2271

Uses. 5-Methyl-3-heptanone is used predominantly as a high-boiling solvent, e.g., for varnish resins.

4. Cyclic Ketones

For cyclohexanone, see → Cyclohexanol and Cyclohexanone.

4.1. Cyclopentanone

Cyclopentanone [*120-92-3*], C_5H_8O, M_r 84.12.

Properties. Cyclopentanone is a colorless liquid with a pleasant, slightly pepperminty odor. It is soluble in water and miscible with common organic solvents.

mp	−51 °C
bp	130–131 °C
d_4^{20}	0.951
n_D^{20}	1.4359
Flash point	30 °C

Production. Cyclopentanone is produced by decarboxylative cyclization of adipic acid [57]. This reaction may be carried out in the liquid phase at 350 °C over zeolites with adipic acid esters [58]. A further production route is oxidation of cyclopentene with oxygen in the presence of palladium (II) chloride or copper (II) chloride as catalyst [59].

Storage and Transportation. Labelling according to GefStoffV [9]: X_i; R phrases: 10–36/38; S phrase: 23. Hazard codes for transportation are as follows:

IMDG Code: class 3.3
RID/ADR: class 3, number 31 c [10]
CFR 49: 172.102 flammable liquid
UN number: 2245

Uses. Cyclopentanone is used in fragrances and as an intermediate in organic synthesis, e.g., for the synthesis of pharmaceuticals (such as cyclopentobarbital), jasmones, or cyclopentylamine. The latter is used for fungicides such as Pencycuron (Bayer). The use of cyclopentanone as a special solvent for polycarbonates has been reported [60].

4.2. Cycloheptanone

Cycloheptanone [*502-42-1*], $(CH_2)_6CO$, $C_7H_{12}O$, M_r 112.17.

Properties. Some physical properties are listed below:

mp	−21 °C
bp	179 °C
d_4^{20}	0.951
n_D^{20}	1.4611
Flash point	55 °C

Production. Cycloheptanone is produced by cyclization and decarboxylation of suberic acid (1,8-octanedioic acid) or suberic acid esters in the gas phase at 400–450 °C over alumina doped with zinc oxide or cerium oxide [61].

Uses. Cycloheptanone is a precursor for syntheses, in particular for pharmaceuticals (e.g., Bencyclane, a spasmolytic agent).

4.3. Higher Cyclic Ketones

Higher cyclic ketones include those compounds that are easily accessible from the products of olefin oligomerization over nickel catalysts (see also → Cyclododecanol, Cyclododecanone, and Laurolactam).

Properties. The higher cyclic ketones are colorless solids, each with a characteristic odor. Only cyclodecanone, used as a precursor for laurolactam, possesses significant importance; the others are used as fragrances or as intermediates. Physical properties are listed in Table 2.

5. Unsaturated Ketones

5.1. 3-Buten-2-one

3-Buten-2-one [*78-94-4*], methyl vinyl ketone, $CH_2{=}CHCOCH_3$, C_4H_6O, M_r 70.09.

Properties. 3-Buten-2-one is a colorless liquid with a penetrating odor. The compound is soluble in water and in organic solvents.

bp	81.4 °C
d_4^{20}	0.842
n_D^{20}	1.408
Flash point	−6 °C
Ignition temperature	370 °C

Pure 3-buten-2-one is stable only below 0 °C; it polymerizes rapidly at room temperature. It is stabilized for storage and transportation by the addition of hydroquinone and glacial acetic acid (0.1 wt % each).

A characteristic reaction of 3-buten-2-one is the addition of nucleophiles (e.g., amines [62] or alcohols) at the carbon–carbon double bond. Michael addition to 3-buten-2-one has been developed into a valuable preparative method in terpene and steroid synthesis; this specific reaction is known as Robinson annelation [63]. The dimerization to 2-acetyl-6-methyl-3,4-dihydro-2*H*-pyran is frequently observed as a side reaction in reactions with 3-buten-2-one.

Production. Two synthetic routes are industrially important [64]:

1) The Mannich reaction of diethylamine, acetone, and formaldehyde [65]:

$$CH_3COCH_3 + HCHO + (C_2H_5)_2NH \cdot HCl \xrightarrow{100\,°C} CH_3COCH_2CH_2N(C_2H_5)_2 \cdot HCl \xrightarrow{150-200\,°C} CH_3COCH{=}CH_2 + (C_2H_5)_2NH \cdot HCl$$

The diethylamine hydrochloride released by thermolysis of the Mannich base can be recycled for use in the reaction with acetone and formaldehyde.

2) Condensation of acetone with formaldehyde [66], [67] and subsequent elimination of water:

$$CH_3COCH_3 + HCHO \longrightarrow CH_3COCH_2CH_2OH \xrightarrow[-H_2O]{H^+} CH_3COCH{=}CH_2$$

The water can be eliminated from 4-hydroxy-2-butanone in the liquid or gas phase. Singlestep processes are also known [68].

Storage and Transportation. 3-Buten-2-one can only be stored in stabilized form at room temperature. Hazard codes for transportation are as follows:

IMDG Code: class 3.2
RID/ADR: class 3, number 3 b
CFR 49: 172.101/102 flammable liquid
UN number: 1251

Table 2. Physical properties of higher cyclic ketones

	CAS registry number	Empirical formula	*mp*, °C	*bp*, °C (kPa)	d_4^{20}
Cyclooctanone	[*502-49-8*]	$C_8H_{14}O$	42	74 (1.6)	0.959
Cyclodecanone	[*1502-06-3*]	$C_{10}H_{18}O$	29	107 (1.7)	0.958
Cyclododecanone	[*830-13-7*]	$C_{12}H_{22}O$	61	125 (1.6)	0.906
Cyclotetradecanone	[*3603-99-4*]	$C_{14}H_{26}O$	53	155 (1.6)	

Uses. The Diels – Alder adduct with cyclopentadiene, methyl (5-norbornen-2-yl) ketone, is used as a precursor for pharmaceuticals such as Akineton (Knoll). Derivatives of α-vinyl lactic acid nitrile (from 3-buten-2-one and hydrocyanic acid) are used as fungicides, e.g., Ronilan (BASF).

The most important product based on 3-buten-2-one is 3-methyl-2-penten-4-in-1-ol, a building block in an industrial synthesis of vitamin A.

5.2. 3-Methyl-3-buten-2-one

3-Methyl-3-buten-2-one [*814-78-8*], methyl isopropenyl ketone, C_5H_8O, M_r 84.12.

Properties. Methyl isopropenyl ketone is a water-clear, lachrymatory liquid with a pungent odor.

mp	− 54 °C
bp	98 °C
d_4^{20}	0.855
n_D^{20}	1.4236
Flash point	5 °C
Solubility in water (20 °C)	5 wt %

3-Methyl-3-buten-2-one shows the typical properties of an α,β-unsaturated ketone, such as the Michael addition of alcohols and amines, and hetero Diels – Alder reactions. It possesses only limited stability; even at low temperature some cyclodimerization occurs [69].

Under the influence of radical initiators or light, methyl isopropenyl ketone polymerizes to poly(methyl isopropyl ketone) [70]. It is able to undergo copolymerization with suitable monomers such as styrene, butadiene, acrylonitrile, or methacrylic acid esters [71].

Production. 3-Methyl-3-buten-2-one is produced by acid-catalyzed condensation of 2-butanone with formaldehyde in the liquid phase [72]. A further possibility is the methylolization of 2-butanone under alkaline conditions followed by elimination of water:

Storage and Transportation. Hazard codes for transportation are as follows:

IMDG Code: class 3.2
RID/ADR: class 3, number 3 b
CFR 49: 172.101 flammable liquid
UN number: 1246

Uses. 3-Methyl-3-buten-2-one is used predominantly as an intermediate in production of 3-methyl-2-butanone, together with a small amount for production of polymers.

5.3. 4-Methyl-4-penten-2-one

4-Methyl-4-penten-2-one [*141-79-7*], mesityl oxide, $(CH_3)_2C{=}CHCOCH_3$, $C_6H_{10}O$, M_r 98.15.

Properties. 4-Methyl-4-penten-2-one is a colorless, oily liquid with an odor reminiscent of peppermint.

mp	−53 °C
bp	129.5 °C
d_4^{20}	0.855
n_D^{20}	1.4458
Flash point	30 °C
Solubility in water (20 °C)	1.07 wt %

Mesityl oxide forms explosive peroxides on prolonged exposure to atmospheric oxygen. Mesityl oxide can be selectively hydrogenated at the olefinic double bond to give 4-methyl-2-pentanone.

Production. 4-Methyl-4-penten-2-one is the precursor of methyl isobutyl ketone (see Section 2.2) and can be produced from acetone in a single- or a two-step process (→ Acetone, Chap. 8.3.). Pure mesityl oxide is obtained by azeotropic distillation of the crude water-containing product. Subsequent purification by removal of the accompanying impurities, such as mesitylene and phorone [*504-20-1*], is effected by distillation [73].

Storage and Transportation. Labelling in accordance with GefStoffV [9]: X_n; R phrases: 10–20/21/22; S phrase: 25. Hazard classifications for transportation are as follows:

IMDG Code: class 3.1
RID/ADR: class 3, number 31 c [10]
CFR 49: 172.101 flammable liquid
UN number: 1229

Uses. 4-Methyl-4-penten-2-one is used to a small extent as an intermediate in synthesis. Most of it is converted to 4-methyl-2-pentanone by selective hydrogenation. Although 4-methyl-2-pentanone has excellent solvent properties for nitrocellulose, cellulose esters and ethers, copolymers of vinyl chloride – vinyl acetate and other synthetic resins, as well as natural and synthetic rubber, its use as a solvent is limited as a result of its toxicity and chemical instability. The fraction of 4-methyl-4-penten-2-one permitted in solvent systems has been set at 5 vol% (Rule 66 of the Los Angeles, California, Air Pollution Control District).

Some of the numerous possible reactions that mesityl oxide may undergo have been used for the synthesis of products such as Budralazine, an antihypertensive agent [74].

5.4. 3,3,5-Trimethyl-2-cyclohexen-1-one

3,3,5-Trimethyl-2-cyclohexen-1-one [*78-59-1*], isophorone, α-isophorone, $C_9H_{14}O$, M_r 138.21.

α-Isophorone

β-Isophorone

Properties. Isophorone is a colorless liquid with a camphor-like odor. It usually contains 1–3 % of the isomeric β-isophorone (3,5,5-trimethyl-3-cyclohexen-1-one). 3,3,5-Trimethyl-2-cyclohexen-1-one is miscible with aromatic and aliphatic hydrocarbons, aldehydes, ketones, alcohols, esters, and ethers.

mp	−8 °C
bp	215.5 °C
d_4^{20}	0.922
n_D^{20}	1.4775
Flash point	95 °C
Ignition temperature	470 °C
Solubility in water (20 °C)	1.2 wt %

Production. Isophorone is produced by condensation of acetone in the liquid phase at ca. 200 °C and 3.6 MPa in the presence of an aqueous potassium hydroxide solution (ca. 0.1 %). The process steps condensation, separation of unreacted acetone, and hydrolysis of byproducts can be carried out in a single reactor [75]. Reaction in the gas phase at 350 °C over calcium – aluminum oxide has also been reported [76].

Storage and Transportation. The following regulations apply for storage and shipping: Labelling according to GefStoffV [9]: X_i (Appendix I.2.1); R phrase: 36/37/38; S phrase: 26; VbF: class A III [11]. Hazard classifications for transportation are as follows [10]:

RID/ADR: class 3, number 32 c.

Uses. As a cyclic unsaturated ketone, isophorone can be aromatized to 3,5-dimethylphenol or 2,3,5-trimethylphenol [77].

Hydrogenation leads, depending on conditions, to 3,3,5-trimethylcyclohexanone or 3,3,5-trimethylcyclohexanol, from which trimethyladipic acid is obtained by oxidation [78]. Trimethyladipic acid is used for the production of 2,2,4-trimethylhexamethylenediamine, which is a precursor for polyamides and polyurethanes.

Addition of hydrogen cyanide to the olefinic double bond [79], followed by amination of the keto group in the presence of hydrogen [80], gives 3,5,5-trimethyl-3-aminomethylcyclohexylamine [*2855-13-2*], isophorone diamine. Reaction of the latter with phosgene gives isophorone diisocyanate [*4098-71-9*]. Both compounds are used in large quantities for the production of polymers, mainly polyurethanes. Worldwide production capacity for isophorone is ca. 50 000 t/a.

6. Diketones

6.1. 2,4-Pentanedione

2,4-Pentanedione [*123-54-6*], acetylacetone, $CH_3COCH_2COCH_3$, $C_5H_8O_2$, M_r 100.11.

Properties. 2,4-Pentanedione is a colorless liquid with a mild ketone-like odor; it is completely miscible with common organic solvents.

mp	−23 °C
bp	140.4 °C
d_4^{20}	0.975
n_D^{20}	1.4510
Flash point	34.5 °C
Ignition temperature	350 °C
Solubility (water, 20 °C)	16 wt %

The chemical properties of 2,4-pentanedione are determined by the keto–enol tautomerism that exists in all states of aggregation:

The equilibrium position is influenced by the state of the ketone (i.e., liquid, solid, gas), the temperature, and the solvent. For example, the liquid at 20 °C contains 18 % ketone and 82 % enol.

As a trifunctional compound with two carbonyl groups and an activated methylene group, 2,4-pentanedione is particularly suitable for the synthesis of heterocycles; these may be formed by reaction of both carbonyl groups or of one carbonyl group and the activated methylene group [81]. For example, reaction with hydrazine leads to 3,5-dimethyl pyrazoles (**1**); with hydroxylamine 3,5-dimethylisoxazole (**2**) is formed; with amidines, ureas, thioureas, or guanidines, 2,4-dimethylpyrimidines (**3**) are obtained; with chloroacetaldehyde 2-methyl-3-acetyl furan (**4**) is formed. The best known reaction of 2,4-pentanedione is the formation of metal acetylacetonates (**5**) [82] (see top of page).

Production. 2,4-Pentanedione is produced by thermal or metal-catalyzed rearrangement of isopropenyl acetate [83] (obtained from acetone and ketene [84]):

Isopropenyl acetate vapor is fed at atmospheric pressure through a V2A steel tube with an inner temperature of 520 °C. The hot reaction gases are quenched, condensed, and cooled to 20 °C, whereby the gaseous byproducts carbon monoxide, carbon dioxide, methane, and ketene are separated. The product is purified by fractional distillation.

Other industrially less important processes for the production of 2,4-pentanedione, include the Claisen ester condensation of ethyl acetate

with acetone using sodium ethoxide as condensation agent [85] and the acetylation of acetoacetic acid esters with acetic anhydride in the presence of magnesium salts [86].

Storage and Transportation. 2,4-Pentanedione is sold with a purity of > 99 %. In addition to small amounts of acetone, 2,4-pentanedione contains 0.1 % water (max.) and 0.2 % acetic acid.

The preferred material for storage containers is enamel, because in the presence of atmospheric oxygen and water, 2,4-pentanedione can form acetylacetonates with most metals.

Labelling according to GefStoffV [9]: X_n (Appendix IIc); R phrases: 10 – 22; S phrases: 21 – 23 – 24/25. Hazard classifications for transportation are as follows:

IMDG Code: class 3.3
RID/ADR: class 3, number 31 c [10]
CFR 49: 172.102 flammable liquid
UN number: 2310

Containers of aluminum or V2A steel are suitable for transportation, although coloring of the product may occur.

Uses. 2,4-Pentanedione is used as an intermediate, in particular for the synthesis of heterocyclic substances for biologically active compounds and dyes, and for the production of metal acetylacetonates. Furthermore, 2,4-pentanedione is used as a solvent, and as an absorption and extraction agent, particularly for the separation and purification of metal ions. Another application is for the purification of metal-containing wastewater and for corrosion protection. 2,4-Pentanedione is also used as a component of catalyst systems for polymerization, copolymerization, oligo- and dimerization.

Metal Acetylacetonates. The industrial importance of metal acetylacetonates is due to their stability (e.g., in air) and their solubility in organic solvents, whereby homogeneous catalytic or stoichiometric reactions of metal ions with organic compounds may be carried out.

Production. Metal acetylacetonates are usually produced by reaction of soluble metal salts with 2,4-pentanedione in aqueous or ethanolic solution. A base is required to neutralize and release the anion from the metal salt. Special production processes are used for some compounds.

Uses. Metal acetylacetonates are used predominantly for polymerization (e.g., olefins, styrene, methacrylates, acrylonitrile), for cross-linking (e.g., epoxy resins, olefins), or for the hardening of epoxy resins or unsaturated polyester resins.

Metal coatings formed with metal acetylacetonates (e.g., for solar cells [87]) have been described. A further application is their use as a stabilizer in poly(vinyl chloride) for minimizing changes in color [88].

Metal acetylacetonates can also catalyze reactions such as oxidation, isomerization, hydrogenation, dehydrogenation, esterification and transesterification [89]. A review of the uses of metal acetylacetonates has been published [90].

6.2. 2,3-Butanedione

2,3-Butanedione [*431-03-8*], diacetyl, $CH_3COCOCH_3$, $C_4H_6O_2$, M_r 86.09.

Properties. 2,3-Butanedione is a light, yellow – green liquid, which is readily soluble in all important organic solvents.

mp	− 2.5 °C
bp	88 °C
d_4^{20}	0.9831
$n_D^{18.5}$	1.3933
Flash point	26 °C
Solubility in water (15 °C)	20 wt %

In the presence of alkali 2,3-butanedione readily undergoes self condensation to form compounds with a quinonoid structure.

Production. 2,3-Butanedione can be obtained by oxidation of 2-butanone over a copper catalyst at 300 °C in a yield of ca. 60 % [91]. Production from glucose by fermentation has also been described [92], and also the acid-catalyzed condensation of 1-hydroxyacetone (obtained by dehydrogenation of 1,2-propanediol) with formaldehyde [93].

Dehydrogenation of 2,3-butanediol over a copper or silver catalyst in the presence of air is industrially important [94]. 3-Hydroxy-2-butanone (acetoin) is generally formed as a byproduct.

Storage and Transportation. Hazard codes for transportation are as follows:

IMDG Code: class 3.2
RID/ADR: class 3, number 3 b
CFR 49: 172.102 flammable liquid
UN number: 2346

Uses. 2,3-Butanedione is mainly important as a flavor component (buttery taste). It is used in low concentration in ice cream, baked goods, and margarine.

6.3. Higher α-Diketones

2,3-Pentanedione [*600-14-6*], $CH_3COCOCH_2CH_3$, $C_5H_8O_2$, M_r 100.12:

mp	−52 °C
bp	110–112 °C
Flash point	18 °C

2,3-Hexanedione [*3848-24-6*], $CH_3COCOCH_2CH_2CH_3$, $C_6H_{10}O_2$, M_r 114.5:

bp	129–130 °C
Flash point	28 °C
n_D^{20}	1.4137
d_4^{20}	0.934

Higher α-diketones are found in small amounts in various foods.

Production. Processes used include oxidation of the corresponding diols over a copper or silver catalyst [94], or selective oxidation of the methylene group in the corresponding methyl alkyl ketones with oxygen in the presence of catalysts such as nickel [95].

Uses. These compounds are used as aroma components in alcohol-free beverages and in baked goods.

7. Aromatic Ketones

7.1. Methyl Phenyl Ketone

Methyl phenyl ketone [*98-86-2*], acetophenone, $C_6H_5COCH_3$, C_8H_8O, M_r 120.15.

Properties. Methyl phenyl ketone is a colorless solid or liquid with a characteristic odor.

mp	20 °C
bp	202 °C

Flash point	82 °C
Solubility in water (20 °C)	0.8 wt %

Methyl phenyl ketone is readily soluble in organic solvents. The usual condensation reactions can be carried out at the methyl group.

Production. Most methyl phenyl ketone originates from the Hock process for the production of phenol from isopropylbenzene (→ Phenol); it is isolated from the residue of this process. In addition, acetophenone can be obtained as a main product by selective decomposition of cumene hydroperoxide in the presence of copper catalysts at 100 °C [96]:

A second possibility is the oxidation of ethylbenzene with air or oxygen at 130 °C and 0.5 MPa. Catalysts used include cobalt salts or manganese salts of naphthenic or fatty acids. Conversion of ethylbenzene is limited to ca. 25 % to minimize the byproducts 1-phenylethanol and benzoic acid [97].

A third method is the Friedel–Crafts acetylation of benzene with acetic anhydride, but this is not of industrial importance.

Uses. Methyl phenyl ketone is mainly converted to resins (synthetic resins) by reaction with formaldehyde [98]. It is also used as a photoinitiator for special printing plates as well as for organic syntheses, particularly for pharmaceuticals. Certain derivatives, such as 1-phenylethanol (obtained by hydrogenation) and its acetate, are used as fragrances. Furthermore, methyl phenyl ketone is used for the synthesis of optical brighteners.

7.2. 1-Phenyl-1-propanone

1-Phenyl-1-propanone [*93-55-0*], ethyl phenyl ketone, propiophenone, $C_6H_5COCH_2CH_3$, $C_9H_{10}O$, M_r 134.12.

Properties. 1-Phenyl-1-propanone is a colorless liquid with a flowery odor, insoluble in water, readily soluble in organic solvents. Typical reactions can be carried out at the methylene group, the carbonyl group, and at the aromatic nucleus.

mp	18 °C
bp	218 °C
d_4^{20}	1.009
n_D^{20}	1.5258
Flash point	87 °C

Production. Propiophenone is produced by Friedel – Crafts acylation of benzene with propionic acid chloride in the presence of an equivalent amount of aluminum chloride [99]. Another industrial method is the catalytic ketonization of benzoic acid with propionic acid over a calcium acetate – aluminum oxide catalyst at 440 – 520 °C [100].

Uses. 1-Phenyl-1-propanone is used mainly as an intermediate for pharmaceuticals such as D-Propoxyphen [101], phenylpropanolamine, and Phenmetrazine [102].

7.3. Diphenyl Ketone

Diphenyl ketone [*119-61-9*], benzophenone, $C_6H_5COC_6H_5$, $C_{13}H_{10}O$, M_r 182.22.

Properties. The stable form of diphenyl ketone consists of colorless rhombic prismatic crystals. Several unstable forms with lower melting points also exist. Diphenyl ketone is insoluble in water and readily soluble in organic solvents.

mp	49 – 51 °C
bp	305 °C
d_4^{50}	1.0869
n_D^{45}	1.5975
Flash point	ca. 155 °C

Production. Benzophenone is usually produced by atmospheric oxidation of diphenylmethane in the presence of metal catalysts such as copper naphthenate [103], [104]. Other processes include Friedel – Crafts acylation of benzene with benzoyl chloride or of benzene with phosgene [105].

Storage. Benzophenone should be stored under cool, dry conditions. A temperature above 45 °C should be avoided (risk of caking).

Uses. Diphenyl ketone and substituted diphenyl ketones in particular are used mainly as photoinitiators for UV-curable printing inks and coatings. Diphenyl ketone is also used as an intermediate for pharmaceuticals and agricultural chemicals. It is employed in the perfume industry as a fixative and as a fragrance with a flowery note.

7.4. 4,4′-Diphenoxydiphenyl Ketone

4,4′-Diphenoxydiphenyl ketone [*14984-21-5*], 4,4′-diphenoxybenzophenone, $C_{25}H_{18}O_3$, M_r 366.42.

Properties. 4,4′-Diphenoxydiphenyl ketone, *mp* 148 °C, *bp* 270 °C, is a colorless solid, that is insoluble in water and soluble in organic solvents.

Production. 4,4′-Diphenoxydiphenyl ketone is produced from diphenyl ether and phosgene [106] in the presence of aluminum chloride as catalyst. It may also be prepared by the catalyzed atmospheric oxidation of 4,4′-diphenoxydiphenylmethane [107] or the reaction of diphenyl ether, tetrachloromethane, and aluminum chloride [108].

Uses. 4,4′-Diphenoxybenzophenone is used exclusively for the production of high-performance plastics, e.g., by Friedel – Crafts reaction with aromatic dicarboxylic acid chlorides, such as terephthalic acid dichloride [109].

The plastics display a series of industrially interesting properties, such as long-term heat resistance up to 270 °C, fire-extinguishing properties, and high chemical- and solvent resistance. The polymer is worked by injection molding or spinning.

7.5. 1-Phenyl-2-propanone

1-Phenyl-2-propanone [*103-79-7*], phenylacetone, benzyl methyl ketone, $C_6H_5CH_2COCH_3$, $C_9H_{10}O$, M_r 134.18.

Properties. 1-Phenyl-2-propanone is a colorless liquid with a pleasant odor; it is insoluble in water and soluble in organic solvents.

mp	− 15 °C
bp (1.73 kPa)	100 °C
d_4^{20}	1.015
n_D^{20}	1.5158

Production. 1-Phenyl-2-propanone is produced by catalytic ketonization of phenylacetic acid with acetic acid over an alumina-supported cerium oxide catalyst at 400 – 500 °C [110]. It may also be produced by the rearrangement of phenylpropylene oxide on zeolites [111] or oxidation of 2-phenylpropanol.

Uses. 1-Phenyl-2-propanone is used as an intermediate for the synthesis of pharmaceuticals, e.g., Prenylamine, a coronary vasodilator (Hoechst) [112].

7.6. 2-Hydroxy-1,2-diphenylethanone

2-Hydroxy-1,2-diphenylethanone [*579-44-2*], benzoin, α-hydroxybenzyl phenyl ketone, $C_6H_5COCH(OH)C_6H_5$, $C_{14}H_{12}O_2$, M_r 212.25.

Properties. Benzoin is a colorless solid with an odor similar to that of bitter almonds and camphor, *mp* 133 – 134 °C, *bp* 194 °C (1.6 kPa). It occurs in two enantiomeric forms that can be separated by reacting the acid phthalates with (+)-quinidine in methanol to form diastereomic salts [113]:

S (+)-Benzoin [*5928-67-6*], $[\alpha]_D^{12}$ +120.5° (1.2 g/dL in acetone)

R (−)-Benzoin [*5928-66-5*], $[\alpha]_D^{16}$ − 119.2° (2.8 g/dL in acetone)

Production. Benzoin is usually synthesized by reacting benzaldehyde in the presence of cyanide ions [114].

Uses. Benzoin is the starting compound for the synthesis of benzil [*134-81-6*]. Benzil derivatives are used as photoinitiators in polymerization reactions [115]. Benzoin and its alkyl ethers are also used for this purpose [116].

8. Toxicology and Occupational Health

The LD_{50} values of the ketones discussed in 2, 3, 4, 5, 6, 7 are listed in Table 3.

Table 3. LD_{50} values for ketones [117]

Ketone	Animal	LD_{50}, mg/kg
Methyl Alkyl Ketones		
3-Methyl-2-butanone	mouse (oral)	2 572
	rabbit (dermal)	6 350
4-Methyl-2-pentanone	rat (oral)	2 080
	rabbit (inhalation)	8 000
2-Heptanone	mouse (oral)	730
	rat (oral)	1 670
	rabbit (dermal)	12 600
5-Methyl-2-hexanone	rat (oral)	4 760
2-Octanone	mouse (oral)	3 824
Dialkyl Ketones		
3-Pentanone	rat (oral)	2 140
2,6-Dimethyl-4-heptanone	rat (oral)	5 750
	rabbit (dermal)	16 000
Cyclic Ketones		
Cyclopentanone	mouse (subcutaneous)	2 600
Unsaturated Ketones		
3-Buten-2-one	rat (oral)	31
	rat (inhalation, 4 h)	7 *
4-Methyl-4-penten-2-one	mouse (oral)	710
	mouse (inhalation, 2 h)	10 *
3,3,5-Trimethyl-2-cyclohexen-1-one	rat (oral)	2 330
	rabbit (oral)	1 500
Diketones		
2,4-Pentanedione	rat (oral)	1 000
Aromatic Ketones		
Methyl phenyl ketone	rat (oral)	815
1-Phenyl-1-propanone	rat (oral)	4 490
Diphenylketone	mouse (oral)	> 2 500
	rabbit (dermal)	3 500
4,4′-Diphenoxydiphenylketone	rat (oral)	> 5 000
	rabbit (dermal)	> 2 000
2-Hydroxy-1,2-diphenylethanone	rat (oral)	> 6 400

* Values are given in milligrams per cubic meter.

Methyl Alkyl and Dialkyl Ketones. 3-Methyl-2-butanone is moderately irritating to the skin and eye [116], its TLV-TWA value is 200 ppm or 705 mg/m^3. The MAK value for 4-methyl-2-pentanone is 100 ppm or 400 mg/m^3 [28]. The TLV-TWA value is 50 ppm or 205 mg/m^3. 2-Heptanone is classified as harmful to health. Inhalation of the vapor or aerosols containing the liquid should be avoided. Its TLV-TWA value is 50 ppm or 235 mg/m^3. 5-Methyl-2-hexanone has a TLV-TWA value of 50 ppm or 240 mg/m^3. The TLV-TWA value for 3-pentanone is 200 ppm or 705 mg/m^3. 2,6-Dimethyl-4-heptanone is registered according to GefStoffV as irritant; skin contact should therefore be avoided. The MAK value has been fixed at 290 mg/m^3 [28]; the TLV-TWA value is 25 ppm or 250 mg/m^3. 3-Heptanone has a TLV-TWA value of 50 ppm or 230 mg/m^3.

5-Methyl-3-heptanone is classified as an irritant. Inhalation of the vapor or aerosols containing the compound should be avoided. Its TLV-TWA value is 25 ppm or 130 mg/m^3.

Cyclic Ketones. Cyclopentanone is classified as an irritant (GefStoffV). Inhalation of the vapor or aerosols containing the liquid should be avoided.

Unsaturated Ketones. 3-Buten-2-one is a lachrymator and is highly toxic. Exposure of any kind should be avoided [16].

2-Methyl-2-penten-4-one (mesityl oxide) is regarded as harmful to health (class IId, " mindergiftig "), according to GefStoffV. It possesses a strong lachrymatory effect. Its MAK value is 100 mg/m^3 [28] and its TLV-TWA value is 15 ppm or 60 mg/m^3.

3,3,5-Trimethyl-2-cyclohexen-1-one (isophorone) is classified according to GefStoffV as an irritant (irritates the eyes, throat, and skin). Its MAK value is 28 mg/m^3 [28] and its TLV-TWA value is 5 ppm or 25 mg/m^3.

Diketones. 2,4-Pentanedione is classified as harmful to health (GefStoffV, " mindergiftig "). Contact with the skin and with the eye should be avoided.

Aromatic Ketones. Diphenyl ketone (benzophenone) has been employed for many years in the pharmaceutical and cosmetics industries and is regarded as essentially nontoxic. It is included in the FDA list of substances that may be added to foods. Benzoin is dangerous to health when inhaled or absorbed cutaneously.

Abstract

Lactic acid is a naturally occurring C_3 α-hydroxycarboxylic acid that is a product of anaerobic metabolism of sugars in virtually all living things. It is a colorless to slightly yellow, hydroscopic liquid commercially available in 50–90 wt% solutions. Lactic acid is made industrially by fermentation of carbohydrates or synthetically via the hydrolysis of lactonitrile. Production by fermentation has increased over the last decade as it produces the highly enantiopure L-lactic acid that is needed for food and polymer applications. Historically, foods have been the largest volume application, as lactic acid is a mild-tasting acidulant and food preservative. The use of lactic acid based polymers has increased significantly since ca. 2002. These polymers have the potential to develop into a million-tonne industry over the next 20 years. The commercial lactic acid processes use a variety of sugar for raw materials (sucrose from sugar beets and sugar cane, dextrose from corn), depending on price and availability of these sugars near the plant location. There are also a number of purification processes that are used commercially (lactate ester distillation, distillation, liquid–liquid extraction).

1. Introduction

Lactic acid, 2-hydroxypropionic acid, was discovered in 1780 by the Swedish chemist Scheele [1]. He isolated it from sour milk as an impure brownish syrup. The French chemist Braconnot [2] established that lactic acid could be made by fermentation processes. Industrial manufacture of lactic acid was established in 1881 in the USA. The history of industrial production of lactic acid has been written by Benninga [22]. The scientific literature on lactic acid is extensive due to its important role in metabolic pathways. Ref. [9] describes the properties and chemistry of lactic acid and is an excellent source of information on lactic acid.

2. Properties

2.1. Physical Properties

Lactic acid, 2-hydroxypropionic acid [*50-21-5*], $CH_3CH(OH)COOH$, M_r 90.08, is the simplest hydroxycarboxylic acid with an asymmetrical carbon atom. It occurs as a racemate (DL) and in two optically active forms, L-(+)-lactic acid [*79-33-4*] and D-(−)-lactic acid [*10326-41-7*].

L (+) Lactic acid D (−) Lactic acid

Pure and anhydrous racemic lactic acid is a white crystalline solid with a low melting point [3]. It is difficult to determine its melting point exactly because of the tremendous difficulty in producing anhydrous lactic acid; values range from 18 [3] to 33 °C [4]. Lactic acid undergoes internal esterification to produce lactoyllactic acid (see Section 2.2.1) [5]. If one of the optical isomers is present in excess in lactic acid, this isomer can be isolated by fractional crystallization of the freshly distilled acid from a mixture of equal parts of diethyl ether and diisopropyl ether [6, 7]. The melting point of the pure optical isomers is 52.7 – 52.8 °C. The boiling point of anhydrous lactic acid is approximately 125 – 140 °C at 27 kPa [8].

Because of the very hygroscopic nature of lactic acid, it is normally obtained as a concentrated solution, up to 90 wt %, which is colorless, virtually odorless, and contains a significant amount of lactoyllactic acid and other lactic acid oligomers. It is completely soluble in water, ethanol, diethyl ether, and other organic solvents which are miscible with water. It is virtually insoluble in benzene and chloroform. The distribution of lactic acid between water and some organic solvents can be found in [9].

Synthetically produced lactic acid has historically been optically inactive, i.e., a racemic mixture. Lactic acid produced by fermentation is optically active, and either isomer can be produced depending on the nature of the bacteria. Density [11, 12], viscosity [10, 12], refractive index [12], and conductivity [13] of aqueous lactic acid solutions of varying concentrations are given in Table 1. The dissociation constant K of lactic acid is 1.38×10^{-4} at 25 °C which corresponds to a pK of 3.86. The pH of a 10 wt % aqueous solution of lactic acid is 1.75 [12].

2.2. Chemical Properties

2.2.1. Internal Esterification

Lactic acid, being both an alcohol and an ester, can undergo intermolecular esterification to produce an ester, lactoyllactic acid [*617-57-2*].

Lactic acid Lactoyllactic acid

Another bimolecular ester which can form is 3,6-dimethyl-1,4-dioxane-2,5-dione or lactide [*95-96-5*], a cyclic ester. Lactide has three different forms, L,L-lactide [*4511-42-6*], D,D-lactide [*13076-17-0*], and D,L-lactide [*13076-19-2*], depending on the chirality of the two lactic acid entities making up the lactide molecule.

Lactoyllactic acid Lactide

On further condensation of lactoyllactic acid, polylactic acids can be formed. These are linear polyesters of undefined chain length. Identical chemical structures can also be produced by the ring-opening polymerization of lactide, and in this case the term polylactide is normally used.

Polylactic acid

Commercially available aqueous lactic acid solutions contain varying amounts of lactoyllactic and polylactic acids, depending on the concentration and age of the solution. Solutions as weak as 6.5 wt % contain ca. 0.2 wt % lactoyllactic acid [12]; an 88 wt % lactic solution contains < 60 % free lactic acid [12], and 100 % lactic acid contains only 32 % of the free monomeric acid [16].

2.2.2. Esterification

Synthesis of the lactates of lower alcohols occurs relatively easily by direct reaction with the corresponding alcohol. The yield can be increased by removing the water formed by azeotropic distillation. Lactate esters can also be made by the reaction of alcohols with polylactic acid to produce minimal water [23].

Table 1. Physical data of aqueous lactic acid solutions at 25 °C

Concentration, wt %	Density, g/mL	Viscosity, mPa·s	Refractive index	Conductivity, mS/cm
6.29	1.0115	1.042	1.3390	3.670
25.02	1.0570	1.725	1.3586	3.823
54.94	1.1302	4.68	1.3909	1.530
88.60	1.2006	36.9	1.4244	0.0567

2.2.3. Other Reactions

Lactic acid has the potential to be a low cost feedstock for two important chemicals: propylene glycol (1,2-propanediol) and acrylic acid. Propylene glycol is produced by reducing lactic acid [24]. Propylene glycol production is over 500 000 t worldwide. Acrylic acid is produced by the dehydration of lactic acid [25 – 27]. Acrylic acid represents a market of more than 3 000 000 t worldwide.

Many more different reactions of lactic acid can be found in the literature. Lactic acid is also of great biological importance [9].

3. Production

Lactic acid is produced on an industrial scale by fermentation or a synthetic method. Since ca. 1995, all new lactic acid production capacity has employed the fermentation approach because it produces lactic acid with high chiral purity that is needed for the food and polymer markets.

3.1. Lactic Acid Fermentation [17 – 20]

The fermentation process requires carbohydrates, nutrients, and a microorganism to produce lactic acid via fermentation. The carbohydrates used in fermentation consist predominantly of hexoses or compounds which can be easily split into hexoses, e.g., dextrose, corn syrups, molasses, sugar beet juice, whey [17], as well as rice, wheat, corn, and potato starches. Lignocellulosics have the potential to become a low-cost source of carbohydrates, and the use of pentoses (xylose, arabinose) for lactic acid production may increase as lignocellulosic hydrolysis technology matures [28, 29].

The nutrients required by the microorganisms include soluble peptides and amino acids, phosphates and ammonium salts, and vitamins. In many cases, the peptides and amino acids are a complex nitrogen source such as yeast extract paste, corn steep liquor, corn gluten meal, malt sprouts, soy peptone, and meat peptone. Only a minimal amount of these complex nitrogen sources are used in order to simplify purification of the lactic acid.

During fermentation, the pH of the broth must be controlled between 5.0 and 6.5. Lime (calcium hydroxide), calcium carbonate, ammonium hydroxide, and sodium hydroxide are typically used to neutralize the lactic acid made in the broth to maintain constant pH. Thus, calcium lactate, ammonium lactate, or sodium lactate salts are formed in the fermentation broth.

Many different microorganisms make lactic acid and can be used in high volume production. *Lactobacillus*, *Bacillus*, and *Rhizopus* strains can be used in the conversion of carbohydrates to lactic acid. The Rhizopus fungal strains have the advantage that they do not require a complex nitrogen source, but tend to give lower yields of lactic acid than the bacterial strains. The bacterial strains perform anaerobic fermentations, and the *Rhizopus* strains aerobic fermentations.

Industrial-scale production of lactic acid requires large amounts of bacterial inoculum which must be cultured in an appropriate seed train. Contaminating microorganisms must be severely limited in the seed train and production vessels to achieve high yields and chiral purities.

Lactic acid yields are between 85 and 95 % based on fermentable sugars. Typical fermentation byproducts, such as formic acid and acetic acid, are found in concentrations of less than 0.5 wt %. "Homofermentive" bacterial strains are typically used as they make the least amount of byproducts.

Recent developments in lactic acid fermentation are moving towards the use of genetically engineered yeast strains to produce lactic acid under neutral or low-pH conditions [30 – 32].

These microorganisms have the advantage of using a defined media and the ability to produce lactic acid, not lactate salts, in the broth. The costs of the neutralizing agent (lime), the acidifying agent (sulfuric acid), and the disposal of the byproduct salt (gypsum) are virtually eliminated by low-pH fermentation.

3.2. Lactic Acid Purification

After fermentation, the lactic acid broth needs to be purified for its intended use. For certain food applications, purification may be minimal. For other applications, particularly as monomer for polylactide production, the purification requirements are considerable. The choices of nutrients and microorganism for fermentation have a significant role in purification decisions. The complex nitrogen source and byproducts from the microorganisms are sources of impurities that must be separated. Unit operations to remove residual proteins, amino acids, sugars, cations, anions, and other organic acids are needed.

In all cases, the microorganisms must be removed from the broth. A variety of technologies can be used, depending on which microorganism was used in the fermentation. Bacterial strains can be removed by flocculation under alkaline conditions [33] or ultrafiltration [34]. *Rhizopus* cell morphology must be controlled carefully in the fermenter in order to easily separate it on a filter.

The lactate salts formed in the fermentation must be converted to lactic acid. There are a number of methods to do this, but addition of sulfuric acid to calcium lactate is routinely used in large-scale production. This method forms a low-value byproduct salt, calcium sulfate or gypsum, which has low solubility in water.

Considerable effort has gone into using other processes that would eliminate the production of a byproduct salt, such as water-splitting electrodialysis [35 – 37] and the use of carbon dioxide in conjunction with liquid – liquid extraction [38].

For some food applications, the broth must be passed through activated carbon and ion exchange, and then concentrated to meet the needs of the customer.

Further purification is needed to produce lactic acid for pharmaceutical, polymer, and other applications. A number of large-scale purification processes are used for production.

A purification process of interest is liquid – liquid extraction with long-chain tertiary amines in the organic phase [21, 39 – 41]. In this case the lactic acid is extracted into the organic phase at a relatively low temperature, and then backextracted into water at high temperature to produce a high-quality lactic acid stream. The selectivity for lactic acid over residual sugars and proteins can be high due to acid – amine complexation.

Distillation of lactic acid is possible with proper operating conditions to minimize the formation of lactic acid oligomers that would limit yield [42 – 44]. The distillate of a lactate ester, such as ethyl lactate, can produce a high quality lactic acid stream but has the additional complexity of the esterification and hydrolysis reactions [45 – 47]. The ethyl lactate distillation route could be advantageous for companies also interested in selling ethyl lactate or other lactate esters.

There has also been considerable effort in the purification of lactic acid streams using membranes with electrodialysis [48, 49], and anion exchange [50 – 52], and these operations may find a role in future production plants.

3.3. Synthesis of Lactic Acid

Since the 1960s, racemic lactic acid has also been produced via synthetic routes. The present industrial synthesis of lactic acid is based on the reaction of acetaldehyde with hydrogen cyanide followed by the hydrolysis of the resultant lactonitrile:

Musashino is the last major synthetic lactic acid producer. If a synthetic route were able to produce a chirally pure lactic acid through an enantioselective catalyst at a low cost, this synthetic route could replace some fermentation capacity.

3.4. Construction Materials

Lactic acid is corrosive toward metallic materials normally used in production and processing, especially at high temperatures. Hastelloy, titanium, zirconium, tantalum, niobium, chromium, and molybdenum are resistant to corrosion. The corrosive properties of lactic acid also depend on its concentration; thus, initial evaporation of lactic liquors can normally take place in 316 stainless steel evaporators, but final evaporation to 80 % lactic acid normally takes place in titanium-lined evaporators.

Lactic acid fermentations are carried out at pH 5.0 – 6.5 where corrosion is minimal, but stainless steel fermenters are mainly used for ease of sterilization.

4. Uses

Lactic acid and some of its derivatives (salts and esters) are used in three main applications: foods, polymers, and industrial.

4.1. Food Uses

The food industry is the traditional large consumer of lactic acid and lactate salts. It is mainly used as an acidulant and preservative. Lactic acid has a mild acid taste and does not overpower weaker aromatic flavors. Since it occurs naturally, it does not introduce a foreign element into the food, and its salts are very soluble, thus giving the possibility of partially replacing the acid in buffering systems. Lactic acid and its salts are used in a variety of beverages, candies, meat, and sauces.

Calcium lactate can be used in a variety of foods to make a calcium-enhanced product. Steroyl lactate and its sodium and calcium salts are used in bread.

4.2. Polymers

The fastest growing use for lactic acid is its use as a monomer for the production of polylactic acid or polylactide (PLA). NatureWorks LLC produces PLA via ring-opening polymerization of lactide [53]. Lactide is made by condensation of two lactic acid entities. Applications for PLA include containers for the food and beverage industries, films and rigid containers for packaging, and serviceware (cups, plates, utensils). The PLA polymer can also be spun into fibers and used in apparel, fiberfill (pillows, comforters), carpet, and nonwoven applications such as wipes.

4.3. Industrial Uses

There are a variety of industrial uses for lactic acid and its derivatives. It is used in metal plating, cosmetics, and the textile and leather industry. Lactate esters are used in the manufacture of paints and inks, electronics, and metal cleaning. Agricultural uses include animal feed.

5. Quality Specifications

Pharmaceutical- and edible-grade lactic acids are considered to be of most importance for external sale of lactic acids. Although quality specifications for pharmaceutical-grade lactic acid are laid down in the national pharmacopia in many countries, there is still no defined specification for edible-grade lactic acid. In the USA the specification for edible-grade lactic acid is laid down in the Food Chemicals Codex (FCC). Table 2 compares specifications for pharmaceutical-grade, FFC, and typical edible lactic acid.

6. Analysis

Quantitative analysis of lactic acid can be carried out by titration against sodium hydroxide with phenolphthalein as indicator. This method is only accurate for very weak lactic acid solutions. Stronger solutions contain lactoyllactic acid which must be previously hydrolyzed to lactic acid. This is done by boiling the lactic acid in a measured excess of sodium hydroxide for a few minutes and backtitrating with hydrochloric acid and phenolphthalein as indicator.

A HPLC method is often used in for quantitative analysis in both research and production environments. This method is accurate and can

Table 2. Specifications of lactic acid

	Pharmaceutical grade	FCC (July 1996)	Typical edible grade
Assay, %	88.0	95 – 105[a]	80
Identification		positive test for lactate	
Chloride, %	< 0.008	< 0.1	< 0.02
Citric, oxalic, phosphoric, or tartaric acid		passes test

Ash, %	< 0.1	< 0.1	< 0.1
Sugars		passes test	
Calcium, %	< 0.02		

[a] Of specified concentration.

also quantitatively measure the presence of other entities, e.g., sugars and other organic acids.

To determine the L-(+)- and D-(−)-lactic acid content of a solution, enzymatic methods are used. The enzymes and analyzers are commercially available together with lactic acid solutions of very high individual isomeric purity. Chiral HPLC columns and GC columns are also available to determine chiral purity.

7. Storage and Transportation

Lactic acid is stored in glass, plastic, or stainless steel tanks and is transported and supplied in well-sealed plastic containers.

8. Legal Aspects

Lactic acid is permitted as a food acid by legislation in most countries. In Europe it must conform to the specific criteria laid down in EC Council Directive 96/77/EC and FCC. In the United States, it has GRAS (generally recognized as safe) status.

9. Economic Aspects

Worldwide capacity of lactic acid is about 450 000 t. Table 3 lists major lactic acid producers, plant locations, and capacities. Actual production data are not reported, as the producers are either privately owned or a subsidiary of a much larger company. There are a number of smaller (< 15 000 t) lactic acid producers in China and India. The rise in PLA production will have a significant effect on the lactic acid market. For instance, the scale of lactic acid production plants has increased dramatically. The 180 000 t/a. NatureWorks plant is three to four times larger than the next largest lactic acid plant. Large economies of scale are required to lower the cost of PLA to allow it to compete against incumbent polymers such as poly(ethylene terephthalate), polystyrene, and polypropylene. Large lactic acid plants with lower production costs due to beneficial economies of scale could significantly disrupt the current lactic acid supply and demand balance. PLA will soon become the single largest use for lactic acid, if it is not already.

The recent increase and volatility in oil price (> $ 60/barrel in 2005) has shown the need to move away from oil-based raw materials to the use of annually renewable raw materials where economically viable. PLA pricing is already competitive with many of the incumbent materials and will become more advantageous as oil production peaks in the next 15 – 30 years. The increasing demand for PLA will create a significantly larger lactic acid production base. The Chinese government has recently been supportive of the emerging PLA industry and has

Table 3. Major lactic acid producers

Company	Plant location	Approx. capacity, 10^3 t/a	Comments
NatureWorks LLC	Nebraska, USA	180	For PLA manufacture. Subsidiary of Cargill Inc.
Purac	Netherlands	30 – 50	Subsidiary of CSM
	Spain	20 – 30

Archer Daniels Midland (ADM)	Illinois, USA	20 – 30	
Musashino	Japan	15	Synthetic lactic acid.

envisioned an annual PLA capacity of millions of tonnes by 2025.

10. Environmental Protection

Lactic acid, a naturally occurring organic acid found in many different biological systems, is environmentally safe. Industrial fermentation of lactic acid produces a salt byproduct that is landfilled or incorporated into building materials or used in agriculture. It also produces an aqueous stream that can be treated in a typical wastewater treatment plant.

As more lactic acid goes into making PLA, there are considerable environmental benefits of using PLA over conventional oil-based polymers, including lower CO_2 emissions and wider choice of disposal options that includes composting.

11. Toxicology and Occupational Health

Lactic acid is a nontoxic naturally occurring edible acid used widely in the food industry as an acidulant. However, it is acidic and will cause discomfort if it should come into contact with eyes or broken skin. It can cause eye irritation and must be washed out immediately. The problem of oral toxicity should not arise unless a large quantity is swallowed (LD_{50}: 3730 mg/kg in rats).

1. Lactose

Lactose, milk sugar, $C_{12}H_{22}O_{11}$, 4-*O*-β-D-galactopyranosyl-α-D-glucopyranose [*63-42-3*], M_r 342.30 (anhydrous); monohydrate [*64044-51-5*], M_r 360.31, is the principal carbohydrate constituent of milk of most mammals. Lactose concentration varies from 0 to 9 wt %, being zero in sea lions, 4.0 % in goats, 4.8 % in cows, and 6.7 wt % in humans [1].

α-Lactose

Bartoletti discovered lactose in milk in 1633, and in 1780 Scheele identified its sugar character. The structure was confirmed by synthesis in 1942 by Haskins et al. [2].

1.1. Properties

Lactose exists in two anomeric forms: α- and β-lactose, differing only in the relative positions of the hydrogen and the hydroxyl group at the C^1-atom of the pyranosidic glucose-part. In aqueous solution lactose consists of 61.5 % of β-pyranose and 38.5 % of α-pyranose; the equilibrium between both forms is established by mutarotation ($K_\alpha + K_\beta = 1.74 \times 10^{-4}\ s^{-1}$ at 20 °C) [3]. Lactose usually crystallizes in the form of its α-lactose monohydrate. The anhydrous β-form can only be obtained at crystallization temperatures > 93 °C. Amorphous lactose, which is quite hygroscopic, is a mixture of α- and β-lactose; it can be obtained by rapid drying methods, e.g., spray drying.

1.1.1. Physical Properties

The physical properties are shown in Table 1 and Figures 1 and 2 [1], [4–9].

1.1.2. Chemical Properties

Lactose has the same principle molecular structure as most other disaccharides and differs only in its configuration. Thus, it generally reacts in the same way as other sugars (→ Carbohydrates). Important points of attack are the reducing end of the glucose moiety, the various hydroxyl groups, and the glycosidic bond between the galactose and the glucose moiety [10].

Examples of reaction types are: (1) formation of anhydro derivatives under the influence of heat and radiation and, (2) formation of unsaturated heterocycles by heat in the presence of an acid [11], (3) oligomerization [12], (4) more or less extensive oxidation at various sites by chemical means or catalytically [11], (5) Maillard type reactions with amino compounds [13], (6) isomerization [14], (7) acetalation [15], (8) hydrogenation [16], (9)

alkaline degradation [13], (10) complexation of metal cations [17], (11) glycosidation [11], (12) etherification [13], (13) halogenation [13], (14) esterification [14], and (15) hydrolysis by enzymatic or acid catalysis [18], [19].

1.2. Production

Generally cheese (sweet) whey or casein (acid) whey (→ Cheese, Processed Cheese and Whey, Chap. 7.2.) is used as raw material for production of lactose (see Fig. 3). Today, permeates from the ultrafiltration of milk or sweet whey are also coming into consideration. With all types of raw materials precautions have to be taken regarding the minerals present; calcium salts may give rise to deposits in evaporators.

The liquid whey (ca. 6.5 % dry matter content) is clarified (a) and concentrated in falling-film evaporators (b) to 55 – 65 % total solids. Upon cooling (c), the greater part of the lactose crystallizes as lactose monohydrate. The crystal slurry is transferred to a line of decanters and centrifuges and washed several times. Thus, after drying, milling and fractionation, yellowish lactose (edible grade) of different particle sizes is obtained.

After the washing stage the raw product can be redissolved (i), treated with activated carbon (j) and recrystallized to refined or pharmaceutical grades of lactose. From 1000 kg liquid whey 32.5 kg lactose and 32.5 kg delactosed wheypowder are obtained.

Environmental Protection. To avoid pollution the dryer should be provided with a cyclone to remove the powder from the exhaust air. Fluid cleaning streams must be purified by simple aerobic or anaerobic digestion before entering a public sewage treatment.

1.3. Quality Specifications

Lactose is produced in various grades of purity (see Table 2).

Chemical analyses of lactose are carried out by standard methods, complying with U.S.P./NF, EP, and JP specifications. For details see the Pharmacopeias mentioned.

Table 2. Specifications of various grades of lactose

Lactose grade	Crude	Edible	Pharmaceutical
Lactose, monohydrate, %	98	min. 99.0	min. 99.7
Free moisture, %	0.4	max. 0.3	max. 0.2
Protein (N content × 6.38), %	1.0	max. 0.3	max. 0.1
Ash, %	0.5	max. 0.3	max. 0.1
Riboflavin, ppm	200	50	0

1.4. Uses

In the various uses of lactose the following functional properties are important [14], [18], [20], [21]:

1) free flowability,
2) flavor and taste enhancement,
3) nonhygroscopic, anti-caking, fat-coating properties,
4) adsorption and absorption capacities,
5) ease of solubility,
6) agglomerating and instantizing capacities,
7) slow fermentation plus acid regulation,
8) stability, long shelf life,
9) absence of odor,
10) good compressibility, and
11) moderate sweetness; the concentration-dependent sweetness of lactose is ca. 30 % relative to sucrose

Food quality, i.e., *edible lactose* is used for:

1) infant and baby food,
2) frozen desserts,
3) ice cream,
4) skim milk, condensed milk,
5) dietetic foods,
6) coffee creamers,
7) chocolate and sugar confectionery,
8) bakery products, meat products,
9) canned fruit and vegetables,
10) dry soups, sauces and spices,
11) binder for liquid foods, and
12) fermentation processes

Pharmaceutical-grade lactose is used for: tableting (wet granulation, direct compressing, retableting), capsule filling, hypodermics, pan coating, and as raw material for lactulose and lactitol production.

1.5. Economic Aspects

Production of lactose is especially located in those areas which have a highly centralized cheese production such as Europe, Eastern and Central States of America and New Zealand. Production figures of 1996 are in 10^3 t/a:

World total	500
Europe	275
North America	180
Oceania	45

Areas of application can roughly be divided into pharmaceutics 100 000 t/a (20 %), baby and infant food 150 000 t/a (30 %), human food 190 000 t/a (38 %), fermentation and animal feed 60 000 t/a (12 %).

1.6. Producers

Important producers of lactose are:

Canada:	Saputo Ltd., Montreal
Finland:	Valio, Helsinki
France:	Besnier Bridel SA, Retiers
Germany:	Alpavit, Heising
	BMI, Landshut
	Meggle Milchindustrie GmbH & Co. KG, Wasserburg
	Milei GmbH, Stuttgart
Ireland:	Avonmore Creameries Ltd., Kilkenny
The Netherlands:	Borculo Whey Products, Borculo
	D.M.V. International, Veghel
	DOMO Food Ingredients, Beilen
New Zealand:	Lactose Company of New Zealand, Hawera
United States:	AMPC Inc., Ames IA
	Avonmore Ingredients Inc., Monroe WI
	Foremost Farms USA, Baraboo WI
	Land O'Lakes Inc., Minneapolis MN
	Leprino Foods, Denver CO
	Lynn Proteins Inc., Granton WI
	United Dairyman of Arizona, Tempe AZ
	Wisconsin Whey International Inc., Madison WI

1.7. Physiological Properties [20]

The metabolizable energy of α-lactose monohydrate amounts to -15.7 kJ/g, that of β-lactose to -16.0 kJ/g.

Lactose is less cariogenic than other natural mono- and disaccharides. This results from:

1) A slower rate of fermentation in the tooth-plaque,
2) A lower final acidity in the same environment, and
3) The lack of production of extra-cellular bacterial polysaccharides

Once lactose reaches the intestines it is enzymatically cleaved into glucose and galactose. The lactic acid formed by subsequent fermentation, and the resulting acid pH prevent the growth of undesirable microorganisms.

The intestinal absorption of calcium and other di and trivalent metal ions, such as magnesium, barium, zinc and iron is strongly improved by the presence of lactose. This can be explained by a decrease of the pH in the digestive tract, which increases the solubility and absorbability of the complexed metal ions.

Lactose has moderate laxative properties because its fermentation products increase the osmotic pressure in the large intestine, thus the loss of too much water is prevented by reabsorption.

In Asia, Africa, and South America large parts of the population have difficulties in absorbing lactose, whereas in Europe and North America, $< 8\,\%$ of the population have such difficulties. This so-called lactose intolerance, i.e., clinical phenomena such as flatulence and diarrhoea, is normally caused by a strongly reduced lactase activity in the mucosa of the small intestine, giving rise to malabsorption of lactose. This does not imply, however, that a malabsorber is totally lactose intolerant [17].

Generally lactase activity in adults is ca. 10 % of that of newborns.

2. Derivatives

2.1. Lactulose

Lactulose [*4618-18-2*], 4-*O*-β-D-galactopyranosyl-D-fructose, $C_{12}H_{22}O_{11}$, M_r 342.30, is a synthetic disaccharide in which galactose is linked to fructose. It was first synthesized in 1929 by isomerization of lactose [22].

The first synthesis of lactulose was completely described by MONTGOMERY and HUDSON in 1930 [23]. They prepared lactulose from lactose in an alkaline solution of lime. Lactulose has not been detected in raw milk, but has been found in milk and milk products after heat treatment [24], [25].

Molecular Structure. The molecular structure of lactulose has been elucidated mainly by HICKS [26], [29].

The anomeric composition of lactose depends on the physical state. In solution the anomeric composition appears to be related to temperature [27] (Table 3).

Table 3. Variation in the percent distribution of anomeric forms of lactulose in water with temperature

	25 °C	58 °C	73 °C
ß-Pyranose	61.5 %	54.7 %	52.1 %
ß-Furanose	29.3 %	31.6 %	35.5 %
α-Furanose	7.6 %	11.2 %	12.4 %
Open ketoform	1.6 %	2.5 %	n.d.

In the solid state two crystal modifications have been described; lactulose anhydrate [29] and lactulose trihydrate [28]. Both modifications differ in anomeric composition as shown in Table 4.

Table 4. Percent distributions of anomeric forms in the crystal modifications of lactulose

	Anhydrate	Trihydrate
ß-Pyranose	16.0 %	
ß-Furanose	72.2 %	100 %
α-Furanose	11.8 %	

The coexistence of different anomers in the same crystal structure is often observed in carbohydrate chemistry, because the ability to form hydrogen bonds of comparable energy facilitates cocrystallization.

2.1.1. Properties

Lactulose anhydrate and trihydrate are white, odorless crystalline powders. Its most important properties are as follows:

mp anhydrate [30]	169 °C
mp trihydrate [31]	68 °C
Solubility in water (kg/kg) anhydrate [30]	3.2 (30 °C), 4.3 (60 °C), > 6.2 (90 °C)
Solubility in water (kg/kg) trihydrate [32]	1.3 (5 °C), 1.5 (10 °C), 2.1 (20 °C), 3.1 (30 °C)
Specific rotation $[\alpha]_D^{20}$ [30]	− 51.4 °
Degree of sweetness [33]	0.48 – 0.62 (sucrose = 1.0)
Concentration (% wt) related to refraction index [34]	0.97° Brix (sucrose index scale)

2.1.2. Production

Lactulose is available on the market both as a syrup and as a dry crystalline powder (anhydrate).

Lactulose can be prepared from an alkaline solution of lactose by the Lobry de Bruyn – Alberda van Ekenstein rearrangement (→ Carbohydrates, → Glucose and Glucose-Containing Syrups, Chap. 2.1.). The first synthesis was performed with lime [23]. Since then many catalysts, such as alkali hydroxides [36], [37], magnesium oxide [38], alkali and alkaline-earth aluminates [39] or alkaline-earth sulfite [40], alkali borate [42], [43], alkali tetraborate plus ion-exchange resin [44], anion exchange resin [45], and amines [46] are reported to give good yields or to minimize secondary reactions.

On a industrial scale, lactulose syrup is usually produced by one of two ways:

1) Common lactulose syrup is prepared by dissolution of lactose in water and addition of sodium hydroxide solution while heating. Because of inevitable degradation reactions the conversion has to be limited. The excess of lactose is removed by crystallization. The solution is deionized using ion exchange resins. A subsequent concentration step leads to a second crop of unreacted lactose.
2) Alternative processes use coreagents such as borate [41] and aluminate [47]. These lactulose complexing agents enable the conversion of lactose to lactulose in a high yield by the prevention of degradation reactions [48]. So higher conversion and selectivity can be reached. Borate or aluminate is subsequently recycled.

The resulting syrup is the common marketed lactulose solution, containing 47 – 53 wt % of lactulose and some other sugars such as lactose, epilactose, galactose, fructose and tagatose. The amount of these related sugars depends on the process used and optional additional purification steps.

Two different processes for obtaining crystalline lactulose anhydrate are used:

1) Further purification of common lactulose syrup by crystallization from alcohols and/or water followed by drying [49].
2) Solidification of an already pure lactulose syrup by well controlled evaporation and stirring, optionally using seed crystals [50].

Two completely different approaches to the synthesis of lactulose, (1) an enzymatic coupling of galactose and fructose using β-galactosidase and (2) an Amadori rearrangement (→ Carbohydrates) of *p*-tolyl-*N*-lactosylamine followed by acid hydrolysis, have been reported [51], [52]. These processes have not found industrial application because of their low yield and intricacy.

Producers. The main manufacturers of lactulose are Solvay (the Netherlands and Canada), Inalco (Italy), Leavosan (Austria), Morinaga (Japan) and Danipharm (Denmark) producing about 12 000 t/a for medical and pharmaceutical uses.

2.1.3. Quality Specifications

Lactulose, both the syrup and the crystalline anhydrate, is a pharmaceutical product and its specifications are laid down in, e.g., the U.S. Pharmacopeia, European Pharmacopoeia, and Japanese Pharmacopoeia.

2.1.4. Toxicology and Physiology

Toxicology. Lactulose administration has not been reported to cause adverse side effects nor does it accumulate in the recipient. Therefore its intake is considered to be safe.

In oral administration, the acute toxicity is at the same level as found for sucrose (male rat 25 g/kg, female rat 28 g/kg) [53], [54].

Physiology. The significance of lactulose was recognized by PETUELY in 1957 when he discovered that lactulose plays an important role in infant nutrition as a "Bifidus Factor" to increase the prevalence of *Bifidobacterium* in the intestinal tract [55].

Most orally administered di-, oligo- and polysaccharides are split by intestinal enzymes into monosaccharides which are absorbed and enter the peripheral circulation. Lactulose, however is not hydrolyzed in the human small intestine and is consequently not absorbed [55]. Most of it is transported to the large intestine, where it is metabolized to low molecular mass organic acids by lactobacilli (*Bifidobacterium*).

Lactobacilli suppress harmful intestinal bacteria, assist in digestion and absorption, produce vitamins, and stimulate immune responses. Lactulose is effective in promoting the proliferation of lactobacilli. Moreover, lactulose does not raise blood glucose levels or influence insulin secretion [56], [57]. Since it is not hydrolyzed in the mouth, lactulose does not promote dental caries [58].

2.1.5. Medical and Pharmaceutical Uses

The main application of lactulose is in humans for the treatment and prevention of portal systemic encephalopathy (PSE) and chronic constipation [59]. Lactulose is an effective laxative because it is cleaved in the colon by lactobacilli to low molecular mass organic acids. This leads to a lowering of the pH of the colon contents and via an increase in osmotic pressure to an increase of the colon contents.

The efficacy of lactulose in the treatment of PSE probably also results from its effect on increasing the number of lactobacilli in the colon. As lactobacilli lack urease and other ammonia-generating enzymes, this might result in a decreased faecal urease activity, decreased urea hydrolysis, and therefore decreased ammonia formation.

Consistent with this hypothesis is the fact that when patients with PSE are treated with lactulose a reduction of the elevated arterial and venous blood ammonia levels occurs and lactulose notably improves the disease.

Other therapeutic uses suggested for lactulose include the treatment of salmonellosis [60].

The discovery of the important role of lactulose in the growth of lactobacilli has led to several areas of application in medicine (therapeutics, diagnostics), human nutrition (food additive), and even veterinary science and nutrition. These areas are rapidly increasing in importance.

2.2. Miscellaneous Derivatives

2.2.1. Lactobionic Acid

Lactobionic acid [*96-82-2*] is used as a carrier for antibiotics and prepared on a small scale by electrochemical oxidation [61].

Lactobionic acid

2.2.2. Hydrolyzed Lactose Syrup

Lactose is hydrolyzed by enzymatic processes and yields a syrup after concentrating. By this procedure solubility is increased to 60 % total solids and sweetness becomes 0.70 relative to sucrose. Most hydrolysis procedures however are applied to deproteinized/demineralized permeates, (demineralized) whey and milk products [20].

1. Introduction

It is more than one hundred years since the first viable incandescent lamp was produced industrially with a sufficiently long operating life. Most major advances in light sources are the result of the discovery and development of new materials. Two such examples are fluorescent powders and translucent ceramic envelopes which led to the development of fluorescent lamps and high-pressure sodium lamps, respectively. Worldwide research and development continuously improve lamp performance. Figure 1 shows the improvement over the years in the efficiency with which a lamp converts electrical power into light (i.e., luminous efficacy).

General. Light is the visible part of the electromagnetic spectrum and extends from about 380 to 760 nm. The response of the eye to the spectral stimulus is described by the *spectral luminous efficiency* $V(\lambda)$ which is depicted in Figure 2.

Types of Lamp. A light source is a device for converting energy into light. A radiation source is similar to a light source but is optimized to radiate in the IR ($>$ 760 nm) or the UV ($<$ 380 nm) region and is often used for industrial or medical applications.

Although a large number of ways exist to generate light, only a limited number of processes are applied in lamps. The main considerations for a practical light source concern conversion efficiency, color aspects, lamp life, and economic factors. In practice almost all light sources convert electrical energy into light and comprise incandescent lamps and gas discharge lamps. Conversion of chemical energy takes place in combustion flash lamps, flames, and candles.

In an *incandescent lamp,* electrical energy is transformed into thermal radiation by heating a coiled tungsten wire to temperatures in the range 2700 – 3300 K (see Section 2.1). The tungsten coil is enclosed in a transparent vessel of glass or fused silica. The medium in the vessel may be a vacuum or an inert gas (normal lamps), or an in-

ert gas with a small amount of gaseous halogens (halogen lamps).

Figure 2. The spectral luminous efficiency $V(\lambda)$ as a function of wavelength λ

In *gas-discharge lamps,* electrical energy is converted into radiation by passage of an electrical current through an ionized gas enclosed in a vessel of glass, fused silica, or translucent alumina. An ionized gas is a mixture of free electrons, positive ions, and neutral species, which is usually referred to as a plasma. The majority of discharge lamps has interfaces between the plasma and the solid conductors in the form of electrodes. In the 1990s, also electrodeless lamps have been introduced in the market (see Chap. 3). Because of the nature of the voltage – current characteristics of discharge plasmas, stable operation of a discharge lamp requires a stabilizing element (or *ballast*) in the electrical circuitry. Furthermore an *ignitor* may be required for converting the neutral gas into a conducting plasma upon switching on the lamp. Discharge lamps are classified as high-pressure or low-pressure, depending on the rate of energy transfer in the discharge (see Section 2.2).

In most discharge lamps the light comes directly from the discharge plasma. In the low-pressure mercury discharge, however, the generated radiation is in the UV region (254 and 185 nm). This "invisible" radiation is converted into light by a fluorescent powder coating on the wall of the discharge vessel (see Section 5.4). In recent years, there has been a breakthrough in the efficiency of light-emitting semiconducting solid-state devices, so-called light emitting diodes (LEDs, see Section 2.3 and Chap. 3).

Quantification of Emitted Light [1]. In a light source the input power results in emission of radiation, which is divided over the spectral range from the ultraviolet to the infrared. The *spectral power distribution* $P(\lambda)$ (expressed in radiated watts per wavelength interval) determines important characteristics of the light source. The *light output* or *luminous flux* (expressed in lumen) is found by integrating the spectral power distribution $P(\lambda)$ multiplied by the spectral luminous efficiency $V(\lambda)$, over the wavelength range. Division of this total lumen

output by the (electrical) input power P_{in}, gives the *luminous efficacy* η in lumens per watt:

$$\eta = k \int_{\lambda} P(\lambda)\, V(\lambda)\, \mathrm{d}\lambda / P_{\mathrm{in}}$$

The coefficient k has a value of 683 lm/W.

Another important quantity related to the luminous flux is the luminance or brightness. The *luminance* gives the luminous flux per unit of solid angle per unit of surface from a given surface and is expressed in candela per square meter, where the candela (cd) is defined as 1 lm/sr (lumen per steradian).

Figure 3. The CIE 1931 (x, y) chromaticity diagram
The blackbody locus (BBL) shows the chromaticity coordinates for black body radiators at the indicated temperatures.

Color. Besides the overall amount of light, the quality of the light, (i.e., color and color rendition) is also very important. Light quality is intimately related to color perception by the human eye. The color of light is indicated by the chromaticity coordinates x and y in the chromaticity diagram, see Figure 3. The (x, y) values are obtained from integrals over the spectral power distribution, weighted by the standardized spectral sensitivity functions, which describe human color perception [1] (→ Dyes, General Survey, Chap. 3.3.). The correlated *color temperature* of a light source corresponds to the temperature of a blackbody radiator with (approximately) the same chromaticity coordinates (cf. Section 2.1). The perception of colored pigments upon illumination with a particular light source is characterized by the *color rendering index* (CRI). This quantity is based on a comparison of the color renditions of the light source in question and a standard source (e.g., a blackbody source or daylight). The maximum value of the CRI is 100 and denotes excellent color rendition. Luminous efficacy and color-related properties are conflicting aspects in lamp design and a compromise always has to be made.

Lighting Systems. The great majority of lamp users are not primarily interested in lamps but require lighting, i.e., provision of the right light at the right place and at the right time. This necessitates a system for creating high-quality lighting at the lowest cost. A lighting system usually consists of (1) a lamp, (2) a ballast – ignitor combination, and (3) a luminaire (a device which directs the light to where it is needed).

The combination of lamp and luminaire is important for obtaining the light distribution required by the user and for minimizing unwanted effects such as glare and stray light. This calls for a coordinated design of lamp and luminaire as in the lighting system for sports arenas shown in Figure 4.

Figure 4. Lamp and luminaire for a lighting system for sports arenas

Ballasts stabilize the current through the discharge in gas discharge lamps. Traditionally, this function has been fulfilled by copper-iron inductive coils [2]. In the last decades the electronic operation of discharge lamps has gained increasing importance [3]. There are several stimuli towards the use of electronics, such as miniaturization, energy saving, control functions, etc. The interaction between a gas discharge and its sta-

bilizing device may be quite complex. To fully exploit the opportunities offered by electronics, an integral system design is required. For example, high-frequency electronic ballasts have been developed for fluorescent lamps. This type of ballast can be used for more sophisticated control functions such as the dimming of lamps according to the amount of daylight and automatic switching off of the lighting system in an empty room.

2. Light Generation

The generation of electromagnetic radiation in the UV, visible, and IR regions of the spectrum involves electrons. In incandescent light sources, the mobile free electrons in the tungsten wire move due to a voltage difference between the ends of the wire. The energy gained by the electrons is transferred to the ionic lattice of the metal by electron – lattice interactions (ohmic heating), which then gives rise to temperature increase coupled with the emission of radiation. Incandescent emission can be described satisfactorily starting from Planck's formula for blackbody radiation (Section 2.1).

For gas discharge lamps, more detailed considerations are required. In the conducting plasma the free electrons are accelerated by the voltage difference between the electrodes. The high-energy electrons collide with gas atoms, leading to excitation of the atoms and subsequent emission of radiation (Section 2.2).

With semiconductor sources (LEDs) the radiation is generated by electron – hole recombination (Section 2.3).

2.1. Thermal Radiation from Solids

The laws of physics underlying the generation of light from solid bodies were proposed around 1900 by PLANCK. Of central importance is blackbody radiation–the radiation present in any region of empty space in thermodynamic equilibrium. Consideration of blackbody radiation yields the maximum amount of radiation that can be emitted by hot solid (i.e., incandescent) bodies. The blackbody radiation $M_0(\lambda, T)$ emitted into a hemisphere per unit area of an ideal surface with an absolute temperature T in the wavelength interval d λ is given by

$$M_0\,(\lambda,T)\,\mathrm{d}\lambda = \frac{2\pi hc^2}{\lambda^5}\,\frac{\mathrm{d}\lambda}{\mathrm{e}^{(hc/\lambda kT)}-1}$$

where $M_0(\lambda, T)$ is expressed in watts per cubic meter, h is Planck's constant (6.63×10^{-34} J · s), k is Boltzmann's constant (1.38×10^{-23} J/K) and c is the velocity of light (3.0×10^{8} m/s). Differentiation of $M_0\,(\lambda, T)$ with respect to T gives the value of the wavelength $\lambda_{\max}$ at which $M_0(\lambda, T)$ has its maximum. This value is given by Wien's law, which states that

$$\lambda_{\max}T = 2.9\times10^{-3}\,\mathrm{m\cdot K}$$

These relationships are illustrated in Figure 5. The value of T at which $\lambda_{\max}$ coincides with the maximum of the spectral luminous efficiency (i.e., 550 nm) is approximately 5500 K, which is about the surface temperature of the sun. Integration of $M_0\,(\lambda, T)$ yields the total radiation $M_0\,(T)$ emitted into the hemisphere per unit area

$$M_0\,(T) = \frac{2\pi^5k^4}{15h^3c^2}T^4$$

which is known as the Stefan – Boltzmann law.

Figure 5. The blackbody radiation M emitted per micrometer of wavelength difference and per unit area into a total hemisphere at various temperatures
The broken line connects the maxima of the curves (Wien's law). The spectral luminous efficiency $V\,(\lambda)$ is also shown.

The thermal radiation $M\,(\lambda, T)$ from surfaces of real materials can be described as

$$M\,(\lambda,T) = \varepsilon\,(\lambda,T)\,M_0\,(\lambda,T)$$

where $\varepsilon(\lambda, T)$ is the emissivity or the emission coefficient of the surface and equals unity for a blackbody radiator. The emissivity equals the absorption coefficient of the radiating body (Kirchhoff's law). A radiator is called "grey" if ε is independent of λ and smaller than unity. If ε depends strongly on λ one speaks of a selective radiator.

The luminous efficacy $\eta(T)$ (expressed in lumen per watt) of a radiator can be written as

$$\eta(T) = \frac{\int_0^\infty V(\lambda)\,\varepsilon(\lambda,T)\,M_0(\lambda,T)\,\mathrm{d}\lambda}{\int_0^\infty \varepsilon(\lambda,T)\,M_0(\lambda,T)\,\mathrm{d}\lambda + \psi}.$$

The term ψ in the denominator represents the energy losses (due to heat conduction etc.) that occur in a real lamp. The function $\eta(T)$ is depicted in Figure 6 for a radiator with constant ε (i.e., a black or grey radiator) and no energy losses (i.e., $\psi = 0$). The form of the function $\varepsilon(\lambda, T)$ may strongly influence the behavior of $\eta(T)$. Metals generally have a decreasing emissivity in the infrared, thus enhancing the luminous efficacy; the luminous efficacy curve for a tungsten surface is also given in Figure 6. Attempts to replace tungsten in incandescent lamps by more selective materials have failed.

Figure 6. Luminous efficacy η as a function of temperature for a black or grey radiator and a tungsten radiator with a smooth surface

The power balance of a typical incandescent lamp is shown in Figure 7; only a relatively small percentage of the input power (8 %) is radiated in the visible wavelength range.

Figure 7. Power balance for an incandescent lamp

2.2. Radiation from Gas Discharges [2], [4]

A metal wire can be considered as a stable plasma consisting of mobile electrons in a lattice of positive metal ions. A gaseous plasma is not stable and requires continuous energy input to prevent it from decaying to a neutral gas. In the plasma column of a gas discharge there is continuous formation and decay of charged particles. The free electrons acquire energy from the electric field between the electrodes. Atoms and molecules are excited and ionized via nonelastic collisions involving the electrons. In the steady state, an equilibrium exists between ionization and the recombination of electrons and ions.

Two types of discharge can be distinguished and discussed in terms of electron temperature T_e and gas temperature T_g. The accelerated electrons can be characterized by a kinetic temperature T_e, often called the plasma temperature. The energy transfer in the discharge is then described as a heat transfer from the electron energy reservoir with temperature T_e to the kinetic energy reservoir of the gas with temperature T_g. Depending on the frequency and effectiveness of the collisional processes, low-pressure discharges occur when $T_e \gg T_g$ and high-pressure discharges when $T_e \geq T_g$. The emphasis on pressure comes from the importance of collisional

frequencies, which are directly related to the gas pressure.

In *high-pressure discharges* (for typical pressures, see Table 2), energy transfer is very effective due to the strong interactions of the various plasma constituents. Recombination of electrons and ions takes place mainly in the gas. These plasmas are close to thermodynamic equilibrium, which allows a physical description by assuming so-called local thermodynamical equilibrium conditions (LTE).

In *low-pressure discharges* (for typical pressures, see Table 2) the interactions between the plasma constituents are weak and recombination mainly takes place at the wall of the discharge vessel, so that energy transfer is small. These systems are very far from equilibrium. A physical description therefore requires a detailed consideration of the rate equations for the atomic and molecular processes involved. Table 2 gives a survey of some typical conditions in the important discharges for light production. Since all discharges are enclosed in vessels of transparent or translucent materials with a maximum working temperature of 1500 K, extremely large temperature gradients exist (of the order of 1000 K/mm), especially in high-pressure discharges.

The radiation emitted by discharges is mainly line radiation, originating from excited atoms. In some discharges, band radiation from excited molecules or continuous radiation from electron – ion recombination (e.g., in the xenon discharge) may contribute significantly. Figure 8 gives the atomic energy levels of sodium and mercury atoms. In low-pressure discharges the radiation is almost exclusively emitted by electronic transitions from the lowest excited states to the ground state (resonance radiation). For the low-pressure mercury discharge these are the 254 and 185 nm lines; for the low-pressure sodium discharge these are the Na-D lines at 589 and 589.6 nm. In high-pressure discharges a large proportion of the radiation comes from transitions involving higher energy levels; due to the high collision frequencies the emission lines display more line broadening than those from low-pressure discharges.

In order to understand the spectral power distribution from high-pressure lamps the importance of radiative transport should be emphasized. Consider a plasma column of cylindrical symmetry (Fig. 9). Emission and absorption of radiation take place in all parts of the plasma column. Thus, the radiation observed outside the discharge by a detector or the human eye represents an integral over the optical path in the plasma.

An important distinction can be made between optically "thin" and optically "thick" radiation. If absorption is small (i.e., optically thin), the observed emission contour $I(\lambda)$ resembles that depicted in Figure 9 A. If the absorption is large, the resulting line contour is strongly broadened and at strong absorptions the phenomenon of self-reversal takes place (Fig. 9 B). The spectral features of the high-pressure sodium lamp are largely due to line broadening and self-reversal. In this discharge the temperature at the discharge center is about 4000 K, while at a distance of only a few millimeters the temperature of the envelope wall is about 1500 K. In simplified terms, a core of "hot" emitting sodium vapor is surrounded by a "cold" mantle of absorbing sodium vapor. The phenomenon of self-reversal occurs because the radiation generated in the core is strongly absorbed in the outer mantle, especially close to the wall. Figure 10 shows the characteristic spectral power distributions of some gas discharge lamps.

The power balance of a typical fluorescent lamp is shown in Figure 11. The low-pressure mercury discharge is relatively effective in converting electrical power into radiation but overall only 25 – 30 % of the input power is radiated in the visible wavelength range. For the high-pressure sodium lamp about 30 % of the input power is converted into visible radiation (Fig. 12).

2.3. Radiation from Semiconductors (LEDs)

A semiconductor can have intentional impurities added, which result in excess electrons (*n*-type semiconductor), or the absence of electrons known as holes (*p*-type semiconductors). A $p-n$ junction occurs when a *p*-type and *n*-type semiconductor are brought together. LEDs are basically $p-n$ junctions (see Fig. 13). The $p-n$ junction acts as diode. When the junction is biased with enough voltage in the appropriate direction, current can flow whereby electrons are

Figure 8. Atomic energy levels of sodium and mercury atoms
The wavelength is given in nanometers.

Figure 9. Radiative transport in a cylindrical plasma column
The observed emission $I(\lambda)$ is primarily an integral of the local emissions over the path from $-R$ to $+R$. The radiation generated in the volume element at coordinate r, however, is attenuated by absorption on its way from r to R. The actual expression for $I(\lambda)$, therefore, is an integral equation involving emission and absorption contributions. The optically thin (A) and optically thick (B) line contours are indicated; the latter shows the self-reversal phenomenon.

Figure 10. Characteristic spectral power distributions of discharge lamps. In all lamps, except for the fluorescent lamp, the spectrum is directly emitted by the discharge. Note the self-reversal of the Na-D lines (590 nm) in the spectra of the high-pressure sodium lamps (e, f). In the fluorescent lamp (a), the Hg resonance radiation at 185 and 254 nm from the discharge is converted to visible radiation by the fluorescent powder (or phosphor). The spectral distribution in the visible is thus determined by the particular phosphor or phosphor mix.

Figure 11. Power balance of a fluorescent lamp

Figure 12. Power balance of a high-pressure sodium lamp

injected into the p-type region where they can recombine with holes. This recombination results in the release of energy in the form of a photon. The wavelength of the photon is determined by the semiconductor energy gap E_g ($\lambda = hc/E_g$). The semiconductor materials used for spectral line radiation at various wavelengths are summarized in Table 1. It can be seen that LEDs with relatively high performance can be fabricated throughout the visible spectrum.

Table 1. Some data on (commercially available) light emitting diodes

Material	Peak wavelength, nm	Typical luminous efficacy at 20 mA, lm/W
AlGaAs	650	8
AlGaInP	560 – 650	22 at 590 nm
		30 at 616 nm
		27 at 628 nm
InGaN	470 – 535	6 at 470 nm
		15 at 505 nm
		22 at 525 nm

Figure 13. Schematic picture of light generation in a $p-n$ junction

White light (i.e., light with an x,y-point on the black body locus, cf. Fig. 3) can in principle be obtained by appropriate combination of blue, green, and red narrow-band emitting LEDs. An essential breakthrough in the generation of white light came in 1995 with the introduction of the blue LED (InGaN). On combination of the blue LED with a fluorescent powder (see Section 5.4) an all-solid-state white light source could be made (white LEDs).

In principle, an efficiency of 100 % for the energy conversion in LEDs can be reached. However, practical difficulties such as material defects, and the problem of extracting the light from the semiconductor chip, result at present in typical conversion efficiencies of the order of 10 %. Improvements in efficiencies are expected to continue as the technology for materials growth and processing continues to evolve.

2.4. Modeling of Lamps

The development of light sources has a long history as an empirical science. During the last decades, however, much effort has been spent in the development of lamp models involving numerical solution of the energy balance, set up in terms of the basic physical mechanisms. Computer programs are now available for modeling both discharge and incandescent lamps with various degrees of completeness, sophistication and accuracy. Although the use of such models is very important as a guide in the development of new and improved lamp types, it has supported rather than replaced the empirical methods used in lamp development.

3. Main Types of Lamps [5]

In this section emphasis is placed on the construction of the main types of light sources; Tables 2 and 3 list important properties. Materials and production processes are described in detail in Chapters 5, 6, 7. Up-to-date reviews on all types of lamps discussed here can be found in the Symposium Proceedings of the International Symposium on the Science and Technology of Light Sources (LS), Kyoto 1995 (LS-7) and Greifswald 1998 (LS-8).

Figure 14. Schematic diagram of an incandescent lamp
a) Fill gas; b) Filament; c) Bulb; d) Support wires; e) Lead-in wires; f) Stem; g) Fuse; h) Lamp cap

Incandescent Lamps. The heart of the incandescent lamp is a tungsten filament that is coiled either singly or multiply and enclosed in a hermetically sealed glass envelope (Fig. 14). A special copper-clad (dumet) wire is used for the glass-to-metal seal. In order to prevent oxidation of the tungsten filament and tungsten transport via the water cycle (see Section 4.2), the impurity level in the glass vessel must be very low.

Table 2. Properties of typical high-pressure and low-pressure sodium and mercury discharge lamps

Property	High-pressure sodium	High-pressure mercury	Low-pressure sodium	Low-pressure mercury (fluorescent)

∗With electrodeless lamps, lamp lives of more than 50 000 h are reached.

Substances known as getters are used to absorb traces of water (see Section 6.1). Usually the vessel is filled with an inert gas (Fig. 14, a) to decrease the evaporation of tungsten from the filament. A more diffuse light source is obtained by etching the inside of the bulb or coating it with a powder layer of TiO_2 (Chap. 7). Colored lamps can be made by using pigments in the powder layer or an exterior heat-resistant paint. The lamp cap is attached to the vessel by means of a cement.

Halogen Incandescent Lamps. In halogen incandescent lamps, the inert gas pressure is higher than in a normal incandescent lamp to further diminish the evaporation of tungsten. For a given design life this means that the lamp can operate at a higher tungsten filament temperature and thus has a higher luminous efficacy. Due to the higher pressures a smaller vessel is necessary. Use of fused silica (commonly called quartz or quartz glass) in place of glass allows the vessel to withstand higher temperatures and pressures. Halogens are used to keep the quartz vessel free from tungsten which evaporates from the filament (see Section 4.2.3). A typical halogen incandescent lamp is shown in Figure 15. Efficacies of halogen lamps can be increased by the use of coatings on the quartz surface, which reflect the infrared radiation back to the filament (see Chap. 7).

The tubular fluorescent lamp (Fig. 16) consists of a glass tube with electrodes sealed in at each end. These coiled tungsten electrodes are coated with a metal oxide mixture which improves electron emission from the electrodes

(see Section 6.3). The lamp is based on the gas discharge in a low-pressure mercury vapor (≈ 1 Pa) and rare gas (≈ 400 Pa) which primarily generates UV mercury radiation. The inner surface of the tube is coated with a fluorescent powder which converts the generated UV radiation into light (see Fig. 10 a). By varying the composition of the fluorescent powder, lamp types with different color appearance and color rendering properties can be made.

Figure 15. Typical halogen incandescent lamp: Automotive head lamp, including mounting construction

Figure 16. Schematic diagram of a fluorescent lamp

Fluorescent (Low-Pressure Mercury) Lamps. In compact fluorescent lamps, the relatively long tube must be folded because simple shortening of the tube leads to an inefficient gas discharge. Examples of compact fluorescent lamps are shown in Figure 17.

Figure 17. Examples of compact fluorescent lamps

Figure 18. An open view of a typical compact fluorescent lamp
a) Outer bulb; b) Discharge tube; c) Ballast/starter circuitry; d) Mounting plate; e) Housing; f) Lamp cap
The narrow discharge tube is multiply folded and integrated into a single unit with the ballast and starter.

As in almost all gas discharge lamps, the lamp voltage of fluorescent lamps decreases as the current increases. This means that a current limiter, usually called a *ballast,* must be placed between the lamp and the mains supply. Also the mains voltage is usually insufficient to ignite the gas discharge so a *starter* or *ignitor* is required. In the regular case, where the ballast is a conventional Cu – Fe coil, this ignitor can be a *glow switch* [2], [3]. The glow switch is a small gas-discharge device, which generates a high-voltage induction peak from the ballast. The mechanism of peak-voltage generation is

Figure 19. Examples of discharge lamps. Note the indicated longitudinal dimensions

interruption of a ballast short-circuit situation. This is caused by thermal closing of the glow-switch bimetal electrodes, as a result of its initial glow discharge. This causes an electrical breakdown in the gas and consequently the creation of a conductive discharge plasma in the lamp. However, with the increasing use of electronic ballasts, the ignition function is usually integrated in the ballast circuitry. The starter and the ballast are often separate from the lamp but may also be integrated into a single unit (see Figs. 18 and 19 a), which can be directly connected to the mains. In such an integral lamp the mercury vapor pressure is very high due to the high wall temperature and an amalgam is used to obtain the optimum mercury vapor pressure (see Section 6.2). A more recent development in low-pressure mercury fluorescent lamps is the electrodeless concept. All major manufacturers now offer fluorescent lamp systems which are based on (high-frequency) inductive coupling of electrical energy into the lamp. The advantage of these electrodeless lamp systems is that the lifetime can be significantly extended compared to lamps with electrodes, where the electrodes usually are the lifetime limiting factor. (see Section 6.3).

Low-Pressure Sodium Lamp. Like the fluorescent lamp, the low-pressure sodium lamp (Figs. 20 and 19 d) is based on a low-pressure discharge but in a sodium – rare gas mixture rather than mercury – rare gas. The fact that sodium is used in place of mercury has significant consequences. Since sodium radiates in the visible region (see Fig. 10 d) a fluorescent powder is not needed, but to obtain a sodium pressure of about 0.5 Pa the gas discharge tube must be at a temperature of about 260 °C. To minimize heat losses, the discharge tube (Fig. 20, a) is folded and placed in an evacuated outer bulb (b) with a getter to ensure a good vacuum throughout life (see Section 6.1). The inside of the outer bulb is coated with a film (typically indium oxide with a tin dope) which reflects in the near infrared and is transparent in the visible (see Chap. 7). At 260 °C sodium attacks normal soda lime glass so the inside of the gas discharge tube is coated with a thin film of sodium-resistant borate glass. The dimples (d) prevent the sodium from forming a film over the whole discharge tube surface.

High-Pressure Mercury Lamp. The high-pressure mercury lamp (Figs. 21 and 19 b), is based on an arc discharge in mercury vapor with a typical pressure of a few hundred kilopascal. The presence of a rare gas at low pressure facilitates ignition. The discharge is compact with a high energy density. In order to withstand the high wall temperatures, the discharge vessel (Fig. 21 b) is made of quartz glass. The tungsten electrodes (d, e) are coated with an emitter material and are sealed into the quartz discharge vessel using molybdenum foil seals. This arc tube assembly is placed in a vacuum or gas-

filled outer bulb (c) which can be clear, frosted, or coated with a fluorescent powder. The high-pressure mercury discharge generates visible radiation and some UV radiation (Fig. 10 b). The latter can be converted to visible radiation by the fluorescent powder on the outer bulb to improve the color appearance and color rendering. A recent development based on the high-pressure mercury discharge is a 100 W lamp for LCD (liquid crystal display) projection applications (Fig. 22). This lamp combines an ultra-high mercury pressure (20 MPa) with a very short arc length (1 – 1.5 mm). The extreme power density in the short arc discharge leads to high arc temperatures and luminance (brightness). In addition a chemical tungsten transport cycle (cf. Section 4.2) is operative. This leads to perfect stability of the light output during lamp lives of more than 10 000 h.

Figure 22. Reflector assembly and burner of the ultra-high pressure mercury lamp for LCD projection

High-Pressure Sodium Lamp. This lamp is based on a high-pressure sodium discharge where the sodium vapor pressure is typically 10 kPa. Normally, mercury is also present with a pressure of ca. 80 kPa. A rare gas facilitates ignition. Under operating conditions Na and Hg are present in the form of a liquid amalgam, the temperature of which determines their actual vapor pressures in the lamp. Due to the high pressure the yellow sodium-D lines are broadened (Fig. 10 e), producing a golden-yellow light rather than the monochromatic yellow produced by the low-pressure sodium lamp (Fig. 10 d). The production of this type of lamp (Figs. 23 and 19 e) only became possible after the development of a material that was resistant to the high sodium pressures at high temperatures ($\approx$ 1500 K). The arc tube consists of translucent polycrystalline alumina (PCA, see Section 5.3). The electrodes are sealed in the PCA tube, using a niobium tube and a sealing frit. The arc tube assembly is mounted in an outer bulb which is usually evacuated, but it can also be filled with an inert gas. The outer bulb contains a getter (see Section 6.1).

Since the 1980s, several modifications of the basic high-pressure sodium lamp concept have been developed and commercialized. The use of a relatively high rare gas (xenon) pres-

sure (typically 200 kPa under operating conditions) has led to an efficacy increase of around 15 %. Furthermore, lamp types with increased sodium vapor pressure (up to about 100 kPa) are available. Under these conditions strong spectral line broadening occurs (cf. Fig. 10 f) leading to the emission of white light. Consequently, the color properties are greatly improved. Finally, environmental considerations have stimulated the development of high-pressure sodium lamps with reduced amounts of Hg. This has resulted in the development of lamp types operating under unsaturated vapor conditions . Recently, even mercury-free lamps types with only a sodium – xenon mixture have been introduced.

Metal Halide Lamp. The discharge vessels for metal halide lamps are made either from quartz glass or from polycrystalline alumina (PCA). The metal halide lamp with quartz vessel is basically similar in construction to a high-pressure mercury lamp, the major difference being that the discharge tube contains one or more metal halides in addition to mercury. The use of metal halides has two advantages:

1) The vapor pressure of the metal halide is usually higher than that of the metal.
2) The metal halides are chemically less aggressive toward quartz glass than the metals.

The halides are partially or wholly vaporized when the lamp reaches its normal operating temperature. The halide vapor dissociates in the hot central region of the arc into the halogen and the metal, and the vaporized metal radiates its characteristic spectrum. The tungsten halogen cycle also operates in some of these lamps. Various metal halide systems have been developed, examples being Na, In, and Tl iodides, Na and Sc iodides, Na and Tm iodides, Dy, Ho, and Tm iodides, and Sn iodides and bromides.

Low-power quartz metal halide lamps have found application in automotive headlighting (Fig. 24). The compact discharge tubes offer a significant improvement in optical performance as compared to halogen lamps. The color requirements for this application are met by the sodium – scandium iodide system. In general, it takes some time for metal halide lamps to arrive at full luminous intensity, due to the vaporization rate of the halide salts. To meet the severe requirements with respect to immediate availability of light upon switching, high-pressure xenon (600 kPa) is dosed. With appropriate ignition and run-up electrical power, a Xe discharge generates the initial light, which is then taken over by the Na – Sc discharge.

Figure 24. 35 W metal halide automotive headlight lamp; the arc length is of the order of 4 mm

A recent development is the so-called *ceramic* metal halide lamp (Fig. 19 c). Instead of a quartz glass tube, a discharge tube of polycrystalline alumina is used. PCA allows discharge vessels with higher wall temperatures than quartz glass. Therefore, higher metal halide vapor pressures can be reached, which result in improvements in efficacy and color properties. A typical metal halide system in these lamps consists of Na, Tl, and Dy iodides. Ceramic metal halide lamps became commercially available in 1993.

Figure 25. Xenon arc lamp

Other Lamp Types. Several other lamps are in use, mostly for specific applications. Some examples are discussed briefly below. An important category of lamps is based on Xe dicharges. The *xenon arc lamp* (Fig. 25) is based on the high-pressure xenon discharge while the *xenon flash lamp* (Fig. 26) is based on a low-pressure xenon discharge. A lamp of possible future importance is the Xe-excimer fluorescent lamp.

This lamp is based on a dielectric-barrier discharge, where excited Xe atoms recombine to Xe_2* excimer molecules, which emit UV radiation at 172 nm. Via an appropriate fluorescent powder visible light can be generated.

Figure 26. Xenon flash lamps

A *low-pressure neon discharge* with its specific red appearance has found application in automotive stoplights.

In the *super high-pressure mercury lamp*, the mercury vapor pressure and the wall loading are extremely high and water cooling of the discharge tube is necessary.

The *carbon arc lamp* and the *zirconium metal combustion flash lamp* are now virtually obsolete. The carbon arc is a high-pressure discharge in air between carbon electrodes. In combustion flash lamps, a light flash with a duration of about 30 ms is generated by the combustion of shreds of zirconium foil in oxygen at pressures of ca. $10^5 - 10^6$ Pa.

A recent discovery is the microwave-excited sulfur discharge lamp. The radiating species is the UV emitting S_2 molecule. Due to radiative transport the wavelength of the emitted radiation is strongly shifted to the visible region. The sulfur discharge itself is very efficient (≈ 170 lm/W). Due to the poor efficiency of microwave generation, the system efficiency is substantially lower.

Light Emitting Diodes. Schematic diagrams of typical LED packages are shown in Figure 27. Basically, the light-generating semiconductor chip is mounted on a carrier with metallic leads and protected by an epoxy dome, which also is instrumental in the outcoupling of the radiation. Typical power inputs per LED vary in the range 50 – 1000 mW. For luminous fluxes comparable to, e.g., incandescent lamps of several tens of watts, therefore, assemblies of LEDs are to be used. At present, the main applications of LEDs are in the signaling area. Due to the trends in efficacy improvement, thermal management, and LED-phosphor systems, together with aspects like long life and reliability, it is expected that LEDs will penetrate into various white-light applications. Present experimental results point into the direction of devices with increased efficacy values as compared to the present alternatives.

4. Lamp Chemistry [6]

4.1. General

The generation of light is mainly based on physical processes. Lamp production, however, depends primarily on the availability of appropriate materials. Light sources can be formulated as: "A variety of chemicals at high pressures and high temperatures during (many) thousands of hours"–a situation which has to be met by the combination of appropriate materials and control of chemical reactions over a long period.

Control of chemical reactions is a key factor in lamp development and engineering. Chemical reactions in the lamp system must be minimized during the required life-times. Chemically induced changes in, for instance, gas or plasma composition, transparency or translucency of the envelope, electron emissive power of the electrodes, or properties of the phosphors should be as small as possible. In this connection, materials processing during manufacturing is of vital importance.

Lamp chemistry covers a broad field since a variety of physicochemical phenomena take place in lamps [6] and belong to such different domains as plasma chemistry, photochemistry, high-temperature chemistry, and solid-state electrochemistry. Above all, however, phenomena related to solid – gas-phase transport chemistry play an important role (Section 4.2).

Chemical processes in lamps can be divided into two categories:

Figure 27. Schematic diagrams of LED packages

1) Processes which are essential for the working mechanism of the lamp. Most important examples here are the chemical transport cycles in halogen incandescent lamps, discussed in Section 4.2.3. Other examples are the dissociation reactions of salt vapors in metal halide lamps.
2) Processes related to lamp maintenance and lamp life. Of special importance in this connection is the presence of gaseous impurities (such as water or oxygen) which should be minimized by proper processing during lamp production. Impurities liberated during lamp burning can be handled by getters (see Section 6.1). Other lamp chemical aspects are discussed in the various sections on materials (Chap. 5).

4.2. Transport Chemistry [7]

4.2.1. Principles

In high-temperature light sources, transport of material via the gas phase affects lamp properties during lamp life both negatively and positively. Two types of transport mechanisms (physical and chemical) can be distinguished.

Physical transport, primarily by evaporation, relates to transport of a compound via its own vapor from a site with a high temperature to a site with a low temperature (e.g., evaporation of tungsten in incandescent lamps).

Chemical transport is a mechanism by which a nonvolatile compound (A) is transported to a site with a different temperature by means of a chemical reaction:

$$A\,(s) + B\,(g) \rightleftharpoons C\,(g)$$

At site I, compound A reacts with the gaseous transport agent B to form the gaseous compound C. The molecules C may reach a site II, for instance by diffusion or convection. If the circumstances at site II are such that C decomposes back into A and B, then A is transported from I to II and transport agent B can take part again in the transfer process. A transport cycle can be formed in which a small quantity of the gaseous transport agent B may cause continuous transport of the nonvolatile compound A. Depending on the reaction, A can be transported to a site with either a lower or a higher temperature.

The rate of chemical transport depends on various factors:

1) *The thermodynamics of the reaction.* Thermodynamic calculations yield the equilibrium vapor pressure of compound C at sites (temperatures) I and II. If substance A is present at both sites, then A will be transferred to the site where the equilibrium vapor pressure of C is lowest. The difference between the vapor pressure of compound C at sites I and II is a measure of the transport rate. The thermodynamics of the transport reaction therefore predict both direction and magnitude of the transport.
2) *Diffusion and convection.* Diffusion is usually slower than convection and offers a way of influencing transport rates.
3) *Kinetics.* The kinetics of the chemical reaction can be so slow that they determine the

rate of transport. For instance, the decomposition of compound C may be inhibited at low temperatures.

High-temperature light sources are complicated chemical systems because they always contain impurities such as oxygen, carbon, and hydrogen which react to form many gaseous compounds. Seldom is a single compound or reaction responsible for chemical transport phenomena. Fortunately in recent decades large thermodynamic data banks combined with powerful computers have become available. Predictions can be made of the direction and magnitude of transport even in complicated systems. Decisive is then the sum of the pressures of all compounds containing A (the element to be transported), each multiplied by a weighting factor equal to the number of atoms of A per molecule of the compound in question: SP (A). Transport will occur from a site with a high value of SP (A) to a site where this parameter is lower.

Figure 28. Vapor pressure of carbon and tungsten
The dashed line gives the summed carbon pressure for a carbon filament lamp containing 1 Pa of oxygen.

A simple example is provided by chemical transport in a carbon-filament incandescent lamp. The carbon vapor pressure curve is given in Figure 28. To keep the transport of carbon to the bulb wall low, the filament temperature should not exceed 2400 K, resulting in a rather inefficient lamp. Transport of carbon to the wall (and thus wall blackening) is strongly enhanced by oxygen impurities via the following chemical transport reaction:

$$C + CO_2 \rightleftharpoons 2\,CO$$

The dashed line in Figure 28 shows the SP (C) as a function of the temperature of carbon when 1 Pa of oxygen impurity is present in the light bulb. At 2300 K the vapor pressure of carbon is about 5×10^{-3} Pa whereas the SP (C) (mainly CO) is 2 Pa. At the cold bulb wall the major component is CO_2 and this leads to a SP (C) of 1 Pa. When the oxygen impurity is present, the difference in SP (C) between the filament and the bulb wall is 1 Pa whereas the corresponding figure for an absolutely clean lamp is 5×10^{-3} Pa. Oxygen impurities therefore strongly enhance wall blackening in this type of lamp. Fortunately, because the wall of a vacuum lamp is cold, the decomposition of CO is slow (kinetic limitation). This means the colder the bulb wall, the slower the blackening due to oxygen impurities. Usually phosphorus is used in lamp manufacture as an oxygen getter (see Section 6.1).

4.2.2. Incandescent Lamps

The vapor pressure curve of tungsten is also given in Figure 28. Depending on the inert gas pressure, filament temperatures in the range 2300 – 2800 K can be applied without running into wall-blackening problems caused by physical transport.

In 1913 Langmuir discovered that residual water vapor causes severe wall blackening by means of chemical transport. The reaction responsible for this is:

$$W + 2\,H_2O \rightleftharpoons WO_2 + 4\,H$$

At the filament, tungsten reacts with water vapor to form gaseous tungsten oxide and hydrogen atoms. At the bulb wall, WO_2 condenses and is reduced by the hydrogen atoms; water is formed and can take part again in the transport process. Essential in this transport cycle is that the hydrogen atoms do not recombine to form molecules because molecular hydrogen is not able to reduce tungsten oxides at the cold bulb wall. In vacuum lamps (residual pressure < 0.1 Pa) the

chance of recombination is small, but also in gas-filled lamps sufficient hydrogen atoms can reach the bulb wall to cause a noticeable reduction of tungsten oxides.

The main sources of water contamination are the glass wall and the coatings with a water-rich (silica) powder. Removal of water is usually not complete after manufacture of the lamp. Getters are used to absorb the residual water vapor in the lamps (see Section 6.1).

4.2.3. Halogen Incandescent Lamps

The efficacy and brightness of incandescent lamps can be improved by using higher filament temperatures but this is limited by wall blackening. In halogen incandescent lamps, this problem is circumvented by increasing the inert gas pressure and using halogens to transport tungsten from the bulb wall back to the filament. Although the principle of this method is fairly old, it was not until 1959 that lamps based on a regenerative iodine cycle were introduced. In 1966 these lamps were further improved by using bromine instead of iodine.

Condensation of tungsten on the bulb wall can be prevented if a gaseous tungsten compound is present which is stable at the temperatures that prevail close to the bulb wall. In lamps containing a small amount of iodine this compound is the oxide halide WO_2I_2 (i.e., besides iodine, traces of oxygen are necessary to make the cycle work). In Figure 29 the calculated vapor pressures of the tungsten-containing species for such a lamp are shown. The SP (W) is plotted as a function of the temperature for the situation that the lamp contains 1 Pa of oxygen and 500 Pa of iodine (pressures during operation). Striking is the minimum in the curve at about 2800 K. The filament temperature is usually above 3000 K and because of the steep temperature dependence of SP (W) in that region, tungsten is transported to sites with a temperature around 2800 K (i.e., to the cooler parts of the filament). The criterion for keeping the bulb wall clean is that the value of SP (W) at the bulb wall should be higher than at the filament (cf. Fig. 29). The consequence of the high value of SP (W) between 800 and 2000 K is that tungsten is transported from sites having these temperatures to sites where SP (W) is minimal (2800 K). Hence colder parts of the lamp such as the filament ends, filament supports, and lead-in wires are attacked. Severe thinning of these colder parts may cause end of life. To prevent this the WO_2I_2 pressure near the wall should not be too high. However, if the WO_2I_2 pressure is too low, blackening will occur. Thus, for a particular lamp design (i.e., bulb wall temperature) the iodine should be dosed within (often) narrow limits. Accurate dosing of iodine is one of the major problems in the production of iodine-cycle lamps.

Figure 29. Calculated vapor pressures of various species in an iodine cycle lamp filled with 500 Pa iodine and 1 Pa (residual) oxygen
The bulb wall temperature is 750 K. The summed vapor pressure SP (W) is also indicated.

Tungsten bromides and oxide bromides are more stable than their iodide counterparts. Hence if the same amounts of iodine and bromine are dosed into separate identical lamps, the SP (W) will be higher in the bromine-containing lamps (Fig. 30) and thus increased attack of the colder parts will occur. This can be diminished by redesigning the lamp such that the bulb wall temperature is lower or by dosing less bromine. A further improvement can be obtained when hydrogen bromide is used instead of bromine (Fig. 30). Hydrogen bromide is a stable compound and only dissociates ap-

preciably near the filament. Thus, in the colder regions of the lamp the free bromine pressure is low and this causes a decrease in the value of SP (W) between 1400 and 2200 K; the attack of colder parts like filament supports is therefore much less. Dosing hydrogen bromide is again a tedious manufacturing task but can be circumvented by using bromohydrocarbon compounds such as mono-, di-, and tribromomethane. Since these compounds are sufficiently volatile and not aggressive at room temperature, they can be easily dosed into the bulb together with the inert gas. When the lamp is burned for the first time these compounds dissociate and carbon dissolves into the tungsten filament.

Figure 30. Summed tungsten pressure SP (W) as a function of the temperature of tungsten for iodine, bromine, and hydrogen bromide cycle lamps
All systems contain 1 Pa oxygen and 1 000 Pa (atomic) halogen.

Chlorine can be used in lamps whose bulb wall temperature is so low that the bromine and iodine cycle do not function (low wattage lamps). Thermodynamic calculations show that in fluorine-containing lamps tungsten can be transported exclusively to the hottest filament sites. However, fluorine compounds are aggressive toward the glass bulb.

4.2.4. Metal Halide Lamps

Quartz Metal Halide Lamps The color rendition and efficacy of high-pressure mercury discharge lamps can be greatly improved by adding small amounts of metal halides to the discharge vessel. In high-pressure mercury discharge lamps the rate at which electrode material (tungsten) is transported to the wall is very low due to the use of emitter material which keeps the maximum temperature of the electrode relatively low (< 2000 K). In metal halide lamps, emitters based on calcium and barium oxide cannot be used (cf. Section 6.3). Consequently the temperature of the electrode tip is usually higher than 2 500 K. This means that one of the problems during lamp life may be wall blackening.

In order to obtain good color properties, high vapor pressures of the metal halides are required: iodides are preferentially used in combination with a high wall temperature. The thermal loading of the bulb wall is limited by softening of the fused silica bulb or by reactions of the metal halides with fused silica. Depending on the desired life of the lamp, the wall temperature is between 1000 and 1300 K. As in halogen incandescent lamps, the bulb wall of metal iodide discharge lamps can be kept clear if tungsten oxide iodides are stable close to the bulb wall. Two types of additive mixtures are used:

1) *Mixtures containing iodides which react poorly with oxygen* (e.g., the iodides of sodium, thallium, indium, and tin). The oxides of these elements are not very stable, oxygen-containing iodide compounds including WO_2I_2 are present in the gas phase. By using a proper combination of additive dose and wall temperature (lamp design), wall blackening can be prevented. In analogy with halogen incandescent lamps, however, colder parts of the electrodes suffer from corrosion (see Section 4.2.3) and this may eventually lead to the electrodes breaking off.
2) *Mixtures containing iodides which react strongly with oxygen.* The advantages of the iodides of scandium and many of the rare-earth metals are their good color-rendering properties and the high luminous efficacy. The oxides of the rare-earth elements are very stable and therefore residual oxygen im-

purities react with the iodides leading to a situation in which there is not enough oxygen left to form WO_2I_2. Lamps containing these iodides consequently suffer from blackening and not from attack of the colder parts of the electrodes. A fortunate circumstance is that the tungsten deposit on the bulb wall does not form a closed, strongly light-absorbing thin layer. Tiny (sub)micron tungsten crystals are formed. As a consequence, the bulb wall is only partially covered with light-absorbing material. Therefore, by optimizing the arc tube design, the lumen loss rate due to wall-blackening can be kept so low, that effective burning times of more than 10 000 h are possible.

Another transport process which may occur in quartz metal halide lamps is transport of silica. This process occurs mainly in lamps containing iodides of category (2). The reaction of rare-earth iodides with silica usually yields a small amount of silicon iodides. These compounds act as transport agents and transport silica from sites with a high temperature to sites with a low temperature. As a result of this etching and deposition, the wall becomes frosted and scatters light.

Ceramic Metal Halide Lamps. Most mechanisms of the tungsten – metal halide chemistry, as discussed above, also apply to ceramic metal halide burners. In addition, corrosive interactions of the salts occur with the alumina wall material. The precise nature of these reactions is still under investigation, but their timescale is such that lamp lives well above 10 000 h are realized (see also Section 5.2.3).

5. Basic Lamp Materials

Materials used for lamp production comprise:

1) Metals, especially doped tungsten (Section 5.1)
2) Envelope materials (glasses and fused silica, Section 5.2, and translucent polycrystalline alumina, Section 5.3)
3) Fluorescent powders (Section 5.4)
4) Special materials such as getters, amalgams, emitters, cements, and marking paints (Chap. 6).

Material aspects of coatings used to modify spectral distribution or spatial distribution of light are discussed in Chapter 7 with special emphasis on interference and semiconductor optical filters.

5.1. Metals [8]

Metals play an important part in the construction of light sources. Table 4 gives a survey of the most important functions of metals applied in lamps.

Table 4. Functions of metals in lamps

Metal *	Lamp component
W (3680 K), W with additions (K, ThO_2, Re)	incandescent filaments
W, W with additions	electrodes
Mo (2883 K), Fe, Ni, Cr, Cu	glass – metal seals
Nb (2741 K)	ceramic – metal seals
Mo	construction elements
Na, Hg	discharge media
Zr, Al, Ba, Ni, Ta	getters
Al, Cu, Zn	lamp caps

* Melting points are given in parentheses.

Tungsten. Tungsten is used for incandescent filaments and electrodes, a successful alternative has not yet been found. The temperature range for incandescent applications varies from 2000 K in small vacuum lamps, through 2700 K in inert gas-filled lamps, up to 3300 K in halogen lamps. The temperature range for electrodes is 1200 – 2800 K. Tungsten has unique properties for these applications. Its melting point (3680 K) is the highest of all metals, its vaporization behavior is favorable, and it displays some selectivity in the emission coefficient (cf. Section 2.1). Moreover its mechanical properties at high temperatures satisfy the required conditions.

Tungsten wire is produced by powder metallurgy. Tungsten powder is compacted into rods (dimensions ca. $20 \times 20 \times 750\,mm^3$), which are sintered to densities some 10 % below the theoretical density ($19\,250\,kg/m^3$). The sintered rods are pressed to wire by rolling, swaging, and wiredrawing. Deformation of metal is always carried out above the brittle – ductile transition temperature to limit work-hardening. Tungsten, therefore, is deformed in the temperature range

1100 – 1900 K. Coiled filaments are prepared by winding tungsten wire on molybdenum mandrels. Dissolving the molybdenum mandrel selectively in nitric acid results in a filament ready to be mounted in the lamp.

Drawn tungsten wire has a fibrous microstructure (see Fig. 31 A), which is sufficiently ductile to accomodate the strains imposed in the coiling process. Upon heating to 1 500 – 2 000 K, recrystallization occurs, resulting in an equiaxed grain structure with an average grain size of the order of the wire diameter (Fig. 31 B). This structure is insufficiently stable with respect to creep (i.e., sliding along grain boundaries) at high temperature. Creep results in distortion and sag of the filament and consequently to short lamp lives.

Figure 31. Tungsten wire
A) Fibrous structure of drawn tungsten wire; B) Equiaxed grain structure of recrystallized pure tungsten wire; C) Interlocking grain structure of recrystallized doped tungsten wire

Creep-resistant tungsten is obtained by doping with small amounts (ca. 100 ppm) of potassium (doped or nonsag tungsten). Potassium is added in the form of a potassium aluminosilicate during the preparation of tungsten powder. Potassium is almost insoluble in the tungsten lattice and therefore remains as potassium "bubbles" in the sintered ingot. The deformation processes, particularly wire drawing, produce rows of potassium bubbles that are aligned parallel to the wire axis. These bubbles act as barriers for grain-boundary movement, especially in the direction perpendicular to the wire axis. This forces grains to grow parallel to the wire axis during recrystallization. The result is an interlocking grain structure, with grain lengths many times the wire diameter (Fig. 31 C). This structure exhibits a sufficient resistance to sliding along grain boundaries (i.e., creep).

The recrystallization temperature of doped tungsten is higher than that of pure tungsten (2000 – 2500 K versus 1500 – 2000 K). Recrystallization is accompanied by embrittlement, which might give rise to difficulties in the handling of coils. Therefore, after the coiling procedure the filament is heat treated below the recrystallization temperature to relieve the stresses due to the coiling. Heating to the recrystallization temperature and thus the formation of the nonsag structure takes place during the processing of the lamp after the mounting of the filament. To ensure satisfactory mechanical properties for filament application close control of the microstructure, especially with regard to the dope distribution during all production stages is essential.

Other additives are used for special-purpose tungsten alloys. Thoriated tungsten (tungsten containing 0.75 – 3 wt % ThO_2) has a fine-grained recrystallization structure. The thoria particles located at grain boundaries impede boundary movements, thus increasing the recrystallization temperature and improving creep resistance. Thoriated tungsten is used for incandescent filaments in lamps with special requirements related to mechanical aspects such as vibration. The material also finds application as electrode material (e.g., in xenon arc lamps). At high temperatures, the thoria is reduced by tungsten, and the released thorium atoms act as an emitter (see Section 6.3). The use of thoria, however, is restricted because of radioactivity safety regulations.

Tungsten – rhenium alloys (3 % Re) have improved mechanical properties (toughness and ductility), furthermore they show improved cor-

rosion resistance, e.g., as high-pressure sodium lamp electrodes.

Molybdenum. The use of tungsten filaments always implies the application of molybdenum. Molybdenum is essential in coilmaking as mandrel material. Molybdenum wire is also used as filament support, while parts such as dimming caps in motorcar lamps are formed out of molybdenum sheet. Molybdenum wire and foils are used as lead-in wires with fused silica lamp envelopes. Fused silica has an extremely low thermal expansion coefficient, so that directly matched seals are not possible. Knife-edged molybdenum foil is sufficiently ductile to deform but not fracture under mechanical stress (see Section 5.2.4).

Niobium. Niobium is used in the ceramic-to-metal seals of high-pressure sodium lamps. Mostly a niobium – zirconium alloy (1 % Zr) is used because of improved ductility. The material is used in the form of deep-drawn or extruded tubes, or as wire (see also Section 5.3).

Other Metals. Composite wires with controlled thermal expansion are used as lead-in wires for glass envelopes (Dumet wires). These wires consist of a low-expansion core (e.g., iron or iron – nickel) and a high-expansion copper cladding. Such compositions are designed to match the expansion of glass (see Section 5.2.4).

5.2. Glass

The most important function of glass in lamps is to provide an envelope for the gas discharge or the glowing filament and its appropriate atmosphere. Soda lime glass was used in the first incandescent lamps and is still in use for most lamp types. The introduction of new discharge lamps, the trends towards miniaturization, and the continuous improvement of the luminous flux have increased the demands on the properties and dimensional accuracy of the glass.

Common characteristics for glasses are that they are hard and brittle, do not have melting points and can withstand relatively high temperatures without deformation. In addition to light, many glasses can transmit radiation in the near IR and UV regions. For a detailed description of the properties and production of glass, see → Glass.

No single glass can meet all the requirements of every type of lamp. The general requirements for the application of glass as lamp envelopes can be formulated as:

1) Good transmission at all wavelengths in the visible spectrum, and a controlled transmission in the ultraviolet region,
2) Adequate thermal shock resistance and adequate mechanical strength at high temperature during lamp operation,
3) Thermal stability (minimal evaporation and degassing) and impermeability to gases during lamp operation,
4) Suitability for making gastight seals to metals for the current feedthroughs,
5) Adequate electrical resistivity at high temperature during lamp operation,
6) Chemical inertness to the atmosphere in the lamp, and
7) Economic forming to the required shapes and the required tolerances.

5.2.1. Production and Composition

The first step in the manufacture of glass is the melting of the mixed raw materials in a furnace. The molten glass is delivered to glass-forming machines where lamp envelopes can be blown in the shape of bulbs or drawn in the shape of tubes. For some lamp types pressed glass parts are used. Close control of bulb and tube dimensions and wall thickness distribution are essential.

Most glasses used in lamps contain SiO_2 as the main component, the so-called glass former. These glasses may be classified into six main types according to their compositions (see Table 5).

Soda lime glass has a composition similar to the glass used for containers and window glass, but is designed to have optimum viscosity and temperature characteristics so that bulbs can be made and processed on high-speed machines. The advantages of soda lime glass are its low cost and easy processability. Disadvantages are its relatively low heat and thermal shock resistance, low chemical stability, and low electrical resistivity. For use in combination with soda

Table 5. Typical compositions and properties of main glass types used in lamps

Glass	Composition, wt %										Softening point, °C	Coefficient of thermal expansion α at 0–300 °C, 10^{-7} K^{-1}	Modulus of elasticity at 20 °C, GPa	Electrical resistivity at 350 °C, $\Omega \cdot$ m
	SiO_2	Na_2O	K_2O	B_2O_3	Al_2O_3	MgO	CaO	BaO	PbO	SrO				
Soda lime glass	72	16	1		2	4	5				700	94	72	10^3
Lead glass	63	7	7		2				21		635	93	61	10^5
Barium glass	67	8	5		4	2	2	9		3	675	93	61	10^5
Borosilicate glass	78	5		15	2						800	40	64	10^5
Aluminosilicate glass	61			1	16		10	12			1 025	45	88	10^9
Vycor	96			4							1 020	7.5	72	10^6
Quartz glass	>99.9										1 140	5.5	73	10^8

lime glass, a lead glass is available for those glass parts, that require higher electrical resistance (see page 26). Because of environmental reasons, however, a barium glass has been developed as a substitute, with almost similar properties.

Pure quartz glass (fused silica) has a superior resistance against heat and thermal shock, chemical stability, and electrical resistivity. The drawbacks of pure quartz glass are its high cost and high processing temperature.

Two types of high-silica glass have been developed which have many of the favorable properties of quartz glass but require lower processing temperatures: Vycor (containing a few percent B_2O_3) and doped quartz glass (made by the addition of a few hundred ppm of oxides like BaO, Al_2O_3, and K_2O to a pure SiO_2 melt).

In comparison with soda lime glass, borosilicate and aluminosilicate glass both have a relatively high thermal shock resistance because of their low thermal expansion coefficient, as well as a relatively high heat resistance and a high chemical stability. Aluminosilicate glass also has a very high electrical resistivity.

5.2.2. Properties

Important glass properties are listed in Table 5.

Mechanical Properties. Glasses are brittle substances with a relatively high modulus of elasticity and reasonable tensile strength, which are almost independent of composition. Characteristic for all kinds of glass is that the practical tensile strength (10 N/mm^2 for sustained stress, 20 N/mm^2 for dynamic or temporary stress) is much lower than the theoretical value (10 000 N/mm^2). This is due to surface defects and stress corrosion. Surface defects act as stress raisers and decrease the practical tensile strength with a factor up to 300. Stress corrosion causes glass to fracture under a sustained stress of 40 % of the mean instantaneous breaking stress. This factor is taken into consideration in the design of glass-to-glass and glass-to-metal seals in lamps. The resistance to thermal shock depends directly on shape, the strength of the glass, and on the reciprocal of the thermal expansion coefficient.

Thermal Properties. The maximum temperature glass can withstand without deformation and the temperature at which glass can be formed are dependent on the viscosity – temperature characteristics; the latter are often identified by specifying viscosity points. For instance, the softening point is the temperature at which the glass deforms under its own weight.

The thermal expansion coefficient is important for glass-to-glass and glass-to-metal seals. A thermal expansion mismatch leads to stresses after cooling to room temperature. With respect to thermal properties, the glasses used in lamps can be divided into three main groups:

1) Soft glasses (soda lime glasses and barium glass) with a thermal expansion coefficient of $(90-100)\times10^{-7}$ K^{-1}
2) Hard glasses (borosilicate and aluminosilicate glasses) with a thermal expansion coefficient of $(35-50)\times10^{-7}$ K^{-1}(The ‘official

boundary' between soft glass and hard glass is the softening point value of 750 °C)
3) High-silica glasses with a thermal expansion coefficient of $(5-7)\times 10^{-7}\ K^{-1}$

A favorable characteristic of glass is the temperature dependence of its thermal conductivity. At low temperatures the thermal conductivity is low, which makes local reshaping possible. The thermal conductivity increases at higher temperatures, enabling processing on high-speed machinery.

Optical Properties. Pure quartz glass has a wide transmission range from 0.18 to 4 µm. Glasses may be rendered colored, translucent, or opaque by the presence of dissolved, colloidal, or crystalline material. Oxides of iron, nickel, chromium, and manganese are some of the materials used to color glass. A controlled amount of iron and/or cerium is often required to absorb unwanted UV radiation. Sometimes special UV transmission demands are imposed on quartz glass (for instance lamps in solaria and photocopy lamps). The absorption edge can be shifted to higher wavelengths by adding titanium dioxide.

Electrical Properties. Glasses are insulators at room temperature. At higher temperatures, soda lime glass shows appreciable electrical conduction with Na^+ and K^+ as the charge carriers. Addition of PbO increases electrical resistance by hindering the mobility of Na^+ and K^+. In the environmentally friendly barium glass, the lead oxide is replaced by BaO and SrO, which fulfill the same function. Alkali-free glasses (aluminosilicate, quartz glass) have a high electrical resistance.

Chemical Properties. Resistance to the lamp atmosphere (sodium, mercury, halogen compounds) at high temperatures imposes special demands on glasses for lamps. Chemical stability of glass at elevated temperatures during lamp operation is necessary. Traces of water vapor and hydrogen must be eliminated. Manufacturing methods and subsequent thermal treatment are important factors. Quartz glass can be used up to 1400 K, although devitrification (i.e., crystallization) may occur at lower temperatures. The onset and the rate of devitrification is accelerated by the presence of impurities (especially alkali metal ions) in the glass or on the surface. The product of devitrification is cristobalite (a crystalline phase of SiO_2) that has a much higher expansion coefficient than quartz glass. This acts as a stress raiser and can cause lamp failure.

5.2.3. Glasses for Lamp Types

Incandescent Lamps. Glasses for the envelopes of incandescent lamps must be suitable for large-scale, high-speed production to keep down production costs. Impurities in the lamp atmosphere such as water vapor, oxygen, carbon dioxide, and hydrocarbons should not exceed levels of a few parts per million. However, soda lime glass is adequate when a good degassing process is provided in combination with a getter. The electrical resistivity of soda lime glass is insufficient for use in the feedthrough at the temperature of operation. The feedthrough and the components carrying the filament support wires must be made of barium glass or lead glass.

A special category comprises pressed glass lamps (special reflector lamps, sealed beam lamps) that are made by using peripheral sealing of reflector and lens pressings of borosilicate glass to enclose an accurately focussed filament assembly.

Tungsten Halogen Lamps. Soda lime glass cannot be used for tungsten halogen lamps due to their high wattage loading. Vycor, aluminosilicate, and quartz glass can be employed. Typical maximum operating temperatures of these glasses are:

aluminosilicate glass	950 K
doped quartz glass	1100 K
Vycor	1200 K
quartz glass	1400 K

With quartz glass there is a chance of crystallization from 1300 K upwards.

Fluorescent Lamps. The provision of drawn tubing (10 – 40 mm diameter) of extremely uniform cross section and wall thickness is vital for the production of fluorescent lamps. For normal fluorescent tubes, a soda lime glass

with a composition that closely resembles that of incandescent lamps is adequate. The composition (especially iron content) is controlled in such a way that radiation below 300 nm is absorbed.

Blackening of fluorescent lamps is a complicated interaction process between the mercury discharge, the fluorescent powder, and the glass; the mobility of sodium ions in the glass is an important factor. For lamps with a high wall loading (compact fluorescent lamps with narrow tubes), a special soda lime glass, lead glass, or barium glass with low alkali ion mobilities has to be used.

Germicidal lamps require high transmission at 254 nm and are produced using a special, highly transmitting sodium barium silicate glass.

Special lamps for use in solaria (low transmission below 280 nm required) and in therapeutic equipment require glass with special UV transmission properties. Sodium barium silicate glass containing titanium dioxide is used.

Low-Pressure Sodium Lamps. The discharge tube of a low-pressure sodium lamp must not be discolored by sodium at the operating temperature of 260 °C. Sodium-resistant borate glass (typical composition: 20 % B_2O_3, 50 % BaO, 5 % SiO_2, 10 % CaO, 5 % MgO, 10 % Al_2O_3) satisfies these demands. However, this glass cannot be formed in the traditional manner. A two-ply tube drawing process is used in which a closely controlled 80-µm thick layer of borate glass is continuously applied over the inside surface of a special soda lime tube.

High-Pressure Sodium Lamps. There are no glasses available that can withstand sodium at the operating temperatures of 800 – 1200 °C. For these discharge tubes, PCA is used (cf. Section 5.3).

High-Pressure Mercury Lamps. Quartz glass is used as the discharge tube material (operating temperature 800 °C). Evolution of hydrogen and/or water vapor from the envelope can be damaging especially because of the long lifetime of this lamp.

The outer bulbs of high-pressure mercury lamps for the higher wattages are made of borosilicate glass and sometimes aluminosilicate glass because of the required temperature and thermal shock resistance. For the lower wattages soda lime glass outer bulbs are used. These outer bulbs, of course, also have to block the transmission of UV radiation.

Metal Halide Lamps. The discharge tubes for metal halide lamps are made from high-quality quartz glass. The quartz glass must have a low hydroxyl content (< 5 ppm) so that evolution of hydrogen or water vapor does not occur during lamp operation. The halide cycle is highly sensitive to even the smallest amounts of water and hydrogen (cf. Section 4.2). Water vapor and hydrogen must be excluded during lamp manufacture. A typical metal halide discharge tube is shown in Figure 32. Quartz glass is permeable for Na^+ ions in the presence of an electric field. Such fields may arise in improperly designed lamps. Transport of Na^+ ions from inside the discharge tube to the outer bulb, gives rise to color drift problems due to changing salt composition. Furthermore, the formation of excess iodine in the discharge causes ignition problems [2]. Transport of Na^+ ions does not take place in 'ceramic' discharge vessels.

Figure 32. A 400-W metal halide discharge tube of quartz glass during the runup of the discharge.
Salt deposits are visible on the wall.

5.2.4. Glass-to-Metal Seals

Glass-to-metal seals are important for all lamp types. The electric lead-in wires are sealed in a stem glass or sealed directly in the bulb by a pinch seal. General requirements for a gastight glass-to-metal seal are:

1) The expansion of the stem glass should match the expansion of the metal from the sealing temperature to room temperature.
2) There should be a good adhesion between the glass and the metal.
3) The glass should retain its electrical resistance at high temperature.

For soft-glass seals, copper-clad wire (Dumet) and alloys of chromium, nickel, and iron are used, mostly sealed into the lead glass or barium glass stem. The wires are preoxidized to obtain a layer of Cu_2O or Cr_2O_3 that ensures good adhesion to the glass. For hard-glass seals (pure quartz glass, Vycor, and doped quartz glass), there is no metal that is both refractory enough and has a matching thermal expansion coefficient. Tungsten and molybdenum have much higher thermal expansion coefficients ($45\times10^{-7}\,K^{-1}$ and $54\times10^{-7}\,K^{-1}$, respectively) than quartz glass ($5.5\times10^{-7}\,K^{-1}$). Seals can be made by using an intermediate sealing glass with a thermal expansion coefficient between that of quartz glass and molybdenum or tungsten, but seals are usually made by pinching or shrink sealing the quartz glass tube over a thin molybdenum foil with a thickness to width ratio of 1 : 100 and a sharp foil edge. As the temperature is lowered after making the seal, the thermal expansion mismatch between the quartz glass and the molybdenum causes stresses to develop rapidly. As soon as the stresses reach the yield point of the molybdenum, they are relaxed by the plastic flow of the metal and further stress development does not occur. This is called the "Housekeeper" technique.

5.3. Polycrystalline Alumina [9]

Polycrystalline alumina (PCA), sintered to translucency, is used as the arc tube material in high-pressure sodium lamps (cf. Fig. 19 e, f), and in ceramic metal halide lamps (cf. 19 c). The first commercial high-pressure sodium lamp was produced in 1965. A complete discharge tube is shown in Figure 33. The tube material in high-pressure sodium lamps is exposed to sodium pressures from 5 to 100 kPa at temperatures ranging from 1000 to 1650 K. The development of a light-transmitting material for use under these conditions was a prerequisite for the realization of high-pressure sodium discharge lamps, since there are no glasses available that can withstand sodium at such operating temperatures. It was found that alumina powder of high (i.e., $>99.9\%$) purity can be sintered to translucency by addition of small amounts of sinter additives (e.g., ca. 0.2 wt % MgO); sintering is typically performed at temperatures of 2100 K.

Figure 33. Typical discharge tube in a high-pressure sodium lamp
A niobium tube, carrying the tungsten electrode, is sealed into the alumina tube using a sealing ceramic
a) Niobium (containing 1 % Zr) current feedthrough; b) Sealing ceramic; c) Polycrystalline alumina tube (presintered polycrystalline alumina plugs and tube are sintered to a monolithic body); d) Brazing material (Ti) to connect niobium and tungsten (or, as an alternative, W – Nb laser welding is used); e) Tungsten rod; f) Tungsten windings with emitter

The use of PCA as tube material for ceramic metal halide lamps enables the operation of metal halide lamps at higher temperatures when compared to the quartz metal halide lamps. This implies that the vapor pressures of the radiating species can be higher than in case of quartz envelopes. Next to improving the color spread between lamps, this leads to improved color rendering and increased efficacies. The first com-

mercial ceramic metal halide lamp was introduced in 1993 (Fig. 19 c).

For PCA lamps a proper vacuum-tight connection between the current feedthrough and the arc tube material had to be developed, which also is chemically resistant to the used lamp filling (i.e., sodium and metal halides, respectively) at the elevated temperatures. The feedthrough region for the high-pressure sodium lamp is depicted in Figure 33.

Arc Tubes. Translucency, with high transmittance in the visible spectrum, and chemical inertness to the used lamp filling at high temperatures are not the only requirements for a ceramic arc tube material. Other requirements are:

1) Sufficient electrically insulating properties at high temperatures,
2) Impermeability for the gas filling enclosed by the arc tube,
3) Low sublimation rate,
4) Sufficient mechanical strength and thermal shock resistance, and
5) Economic feasibility.

Although many materials can be sintered to translucency (such as Al_2O_3, AlN, MgO, Y_2O_3, $Y_3Al_5O_{12}$, Gd_2O_3, Sc_2O_3, $LiAl_5O_8$, BeO, CaO, $3\,Al_2O_3 \cdot 2\,SiO_2$, $3\,Al_2O_3 \cdot 2\,GeO_2$, ThO_2), only a limited number meet the above requirements. At present the envelope material used by all ceramic discharge lamp manufacturers is alumina.

Two types of alumina have been employed as arc tubes: (1) transparent single-crystal alumina tubes grown from a melt, and (2) PCA tubes sintered to translucency at temperatures of about 2100 K from submicron high-purity alumina powders. Although the transparent monocrystalline arc tubes have a somewhat higher corrosion resistance to sodium and give rise to a higher luminous efficacy than PCA arc tubes, the anisotropic character of α-alumina causes considerable stresses leading to cracks and leakages upon the thermal shocks produced when the lamp is switched on and off. This, combined with the higher price of single-crystal alumina, has favored the use of PCA arc tubes.

Shaping of PCA arc tubes can be realized by conventional ceramic processing, such as:

1) Granules of alumina are pressed isostatically in a mold; the alumina granules contain sinter dope and binder and are made by spray drying to obtain proper powder flow characteristics.
2) A well-kneaded aqueous alumina paste containing dope, binder, and lubricant is extruded through an annular opening, the emerging tube being cut to the desired length.

After drying the tubes, well-fitting PCA plugs are inserted, and the assembly is presintered in air at temperatures up to 1700 K. During this process the binder is burned out. The decrease of the mechanical strength of the tubes resulting from binder removal is compensated for by bonding the primary particles to one another during presintering. In arc tubes manufactured by extrusion technology, the shape shown in Figure 33 is obtained by presintering the plugs to such a degree that they fit into the tube bore and shrink somewhat less than the tube during sintering of the assembly. Subsequent sintering to translucency is usually performed in a vacuum or in hydrogen. During (pre)sintering the dimensions of the initial pressed or extruded products decrease by some 20 %. Examples of PCA arc tubes are shown in Figure 34.

Figure 34. Examples of polycrystalline alumina arc tubes The length of the upper arc tube is 78 mm.

Microstructure. The effective removal of residual porosity is essential for obtaining translucent polycrystalline material. Typically, commercial PCA is sintered to more than 99.9 % of the theoretical density. Sinter dopes (such as $MgO, CaO, ZrO_2, HfO_2, CeO_2, Y_2O_3, La_2O_3$ or appropriate combinations) affect both the grain boundary mobility and the mobility of inclusions (pores). These parameters determine the

degree of inter- and intragranular pore entrapment which reduces light transmission due to scattering. The typical structure of a PCA surface is shown in Figure 35.

Figure 35. A scanning electron micrograph of the microstructure of a polycrystalline alumina arc tube surface

The final microstructure determines the optical, mechanical, and chemical properties of the end product. The optical quality of the material is determined by the spectral absorptivity (negligible for alumina in the visible spectrum), the spectral reflectivity (the normal single surface reflectivity is about 8 % for alumina), and the spectral transmittivity. Normal in-line transmission is very sensitive to the scattering properties of the alumina tube which depends predominantly on the residual porosity (distribution) and on the number of grain boundaries in the lightpath (in other words on the mean grain size after sintering). Obviously, optimum optical transparency is realized with single-crystal alumina (sapphire).

The mechanical properties of alumina, and the related thermal shock resistance, are determined primarily by the size distributions of the alumina grains and the residual pores. With increasing grain size the mechanical strength generally decreases, imposing an upper limit on the grain size. The compromise between the desired mechanical and optical properties is a mean alumina grain size of 25 – 40 µm.

High-purity alumina starting material (> 99.98 %) is required to minimize segregation effects (i.e., increased amounts of dopant and unintended impurities located at grain boundaries). When sinter dope levels exceed the solubility of the dope in alumina, precipitation of second phase particles is observed. Such segregation may negatively affect the optical and chemical properties of the PCA tube to a significant extent.

Corrosion. The chemical resistance of the PCA tube material to the lamp filling components is such that appropriate lamp lifetimes can be obtained. Two major types of attack on alumina are observed: (1) frontwise, or bulk alumina corrosion, which is independent on the presence of grain boundaries; and (2) corrosion which proceeds preferentially along the grain boundaries present in the PCA. The latter can result in leakage of the arc tube. Both the presence of sinter dopes and the conditions during sintering determine the chemical properties of the PCA.

In *high-pressure sodium lamps* alumina reacts with sodium to some extent. With sodium pressures up to 10 kPa, the reaction rate is so low, that it allows operational lifetimes from 10 000 to 30 000 h. With higher sodium pressures, the reduction of alumina by sodium is considerable. In addition to the solid-state reaction products ($NaAlO_2$ or $NaAl_5O_8$/$NaAl_{11}O_{17}$), aluminum has also been detected and condenses in the coldest part of the arc tube. The $NaAl_5O_8$/$NaAl_{11}O_{17}$ is formed in the high-temperature zone of the arc tube. Furthermore, emitter material sputtered from the electrode onto the alumina surface enhances the rate of sodium corrosion.

In the recently introduced *ceramic metal halide lamps*, corrosion reactions imply interaction of rare earth iodides with alumina. Many details thereof, however, are still unclear at the moment

Sealing. Niobium was chosen as a current-feedthrough material because its thermal expansion coefficient is very close to that of alumina. Furthermore, as far as high-pressure sodium lamps are concerned, niobium has sufficient chemical resistance to sodium at high temperatures, however it is also permeable to hydrogen; (hydrogen, which arises from moisture in arc tubes, has a negative influence on arc ignition, see Section 6.1). The feedthrough (Fig. 33) is sealed into the PCA tube by means of a sealing ceramic. The gastight seal must (1) show good adhesion to both PCA and niobium, (2) re-

sist the sodium vapor pressure at 900 – 1200 K, and (3) withstand thermal shocks occurring upon switching the lamp on and off. Typical sealant compositions (in weight percent) are: 5.6 MgO, 38.6 CaO, 8.7 BaO, 45.4 Al_2O_3, 1.7 B_2O_3 or 39.2 CaO, 9.3 SrO, 5.2 Y_2O_3, 46.3 Al_2O_3. The sealing ceramic is pressed in the shape of a ring which is positioned around the niobium feedthrough and heated to melting (typically between 1 500 and 1 600 K). The space between the feedthrough and the PCA tube is filled with the molten oxide mixture which must have a sufficiently low viscosity. Upon cooling, fine-grained crystalline phases are formed. The final composition of the seal depends on the initial sealant composition and the applied temperature – time schedule. An optimum seal closely matches the thermal expansion of both alumina and niobium.

With *ceramic metal halide lamps*, sealing is complicated by the fact that niobium reacts with the arc tube filling. Therefore, a more complex feedthrough construction is used, where direct contact between niobium and the arc tube filling is prevented. To realize this feedthrough construction a special end shape of the arc tube is required, in combination with both a specific sealing ceramic and a dedicated sealing process.

5.4. Fluorescent Powders [10]

Fluorescent powders (also called phosphors) for lighting applications are mainly used in combination with low-pressure mercury discharges. They absorb the UV radiation emitted at 185 and 254 nm and efficiently convert it into radiation of a longer wavelength, mostly visible radiation. In low-pressure mercury discharge lamps almost the whole of the emission spectrum is determined by the phosphor. For a detailed description of phosphors see → Luminescent Materials, Chap. 1.

Properties. A fluorescent powder consists of a host lattice doped with a few percent of an activator, which is responsible for the luminescent properties. The host lattices are always inorganic, oxygen-containing materials such as oxides, aluminates, phosphates, borates, or silicates. The activators are metal ions (e.g., Pb^{2+}, Mn^{2+}), in many cases rare-earth metal ions. A well-known phosphor is the halophosphate $Ca_5(PO_4)_3X : Sb^{3+}, Mn^{2+}$ where X = Cl, F. The UV photons are absorbed by the Sb^{3+} ions and the excitation energy is partly emitted in the blue region of the spectrum. The other part of the excitation energy is transferred to the Mn^{2+} ion, which has an orange luminescence; here Sb^{3+} acts as a sensitizer. In most cases the host lattice does not participate in the luminescent process; it does, however, influence the position of the energy levels of the activator ions and consequently the absorption and emission wavelengths.

In the lamp the phosphor layer is in direct contact with the discharge plasma. Therefore, the phosphor should be stable to short-wavelength UV irradiation as well as to ion and electron bombardment over prolonged exposure up to 10 000 h.

Table 6. Important fluorescent powders (phosphors) used in lamps

Material	Emission wavelength
General lighting phosphors	
Broad band emission	broad emission bands resulting in approximately white light
$Ca_5(PO_4)_3(Cl,F) : Sb^{3+}, Mn^{2+}$	
Narrow band emission	
$BaMgAl_{10}O_{17} : Eu^{2+}$	450 nm
$CeMgAl_{11}O_{19} : Tb^{3+}$	545 nm
$Y_2O_3 : Eu^{3+}$	612 nm
UV-emitting phosphors	
Narrow band emission	330 – 370 nm
$BaSi_2O_5 : Pb^{2+}$	
$YPO_4 : Ce^{3+}$	
$LaPO_4 : Ce^{3+}$	
$CeMgAl_{11}O_{19}$	

Types of Phosphors. The most important fluorescent powders are given in Table 6. A distinction can be made between phosphors for general lighting purposes and phosphors for industrial and medical purposes (UV-emitting phosphors). Until 1975 the general lighting market was dominated by the halophosphate lamps containing $Ca_5(PO_4)_3$ (Cl, F): Sb^{3+}, Mn^{2+}. The Sb^{3+} ions yield a blue luminescence, the Mn^{2+} ions an orange one. By adjusting the ratio of the blue to orange luminescence, white light can be obtained; the luminous efficacy of such lamps is 80 lm/W, but the color rendition is moderate and the CRI is only 50 – 60. A high luminous flux and a good color rendition can be obtained by blending three phosphors emitting in narrow wavelength intervals centered at 450, 545, and

612 nm, respectively. Narrow band emission is only found with rare-earth ions, notably Eu^{2+} emitting in the blue, Tb^{3+} in the green, and Eu^{3+} in the red.

The development of rare-earth based phosphors therefore was the crucial step in the development of low-pressure mercury discharge lamps with a high efficiency of 100 lm/W and a CRI of about 85. Recent trends are the application of $Sr_3(PO_4)_5Cl:Eu^{2+}$ instead of $BaMgAl_{10}O_{17}:Eu^{2+}$, while the green aluminate $CeMgAl_{11}O_{19}:Tb^{3+}$ is gradually being replaced by more efficient phosphors, such as $LaPO_4$: Ce^{3+}, Tb^{3+} and $GdMgB_5O_{10}:Ce^{3+}$, Tb^{3+}.

The Super de Luxe lamps, with near perfect color rendition, occupy a smaller but interesting market niche. The spectrum generated in these lamps is more or less continuous, extending from the blue to the deep red. Superior color rendition is obtained at the expense of the luminous flux. The phosphors applied here are based on combinations of those mentioned in Table 6. Lamps with a blend of $GdMgB_5O_{10}:Ce^{3+}$, Tb^{3+}, Mn^{2+}, $Sr_4Al_{14}O_{25}:Eu^{2+}$ and $Ca_5(PO_4)_3(Cl,F):Sb^{3+}$, Mn^{2+} reach CRI values of 95 along with a luminous efficacy of 65 lm/W.

The introduction of rare-earth based phosphors also resulted in a drastic improvement in lamp maintenance. Due to the chemical and thermal stability of these phosphors the wall load could be increased, resulting in a reduction of the tube diameter from 38 to 26 mm, and subsequently to 10 mm.

The luminous efficacy and the color rendition of a high-pressure mercury lamp is enhanced by applying an YVO_4: Eu^{3+} phosphor on the inner side of the outer bulb wall. This phosphor is highly efficient for the transformation of the Hg 254 and 365 nm line radiation into red light at 617 nm up to temperatures of about 300 °C. The UV light is absorbed by the vanadate groups, from which the energy is transferred to the Eu^{3+} activator.

Production and Application. Lamp phosphors are produced by solid-state reaction at elevated temperature in a controlled atmosphere. In view of the poor reactivity of the raw materials (i.e., oxides or carbonates), small quantities of reactive compounds such as halides are often added. The phosphors are prepared as fine-grained particles with a fairly narrow size distribution between 1 and 10 µm. Application on the lamp bulb wall takes place via a flow coating technique. At present coating suspensions are based either on water or on organic solvents (e.g., butyl acetate). The suspension is stabilized by adding chain-type polymers of high molecular mass such as cellulose derivatives. The phosphor powder should be applied as a thin layer of uniform thickness. This is achieved by careful design of the rheological properties of the suspension, combined with appropriate drying conditions. The polymer is removed in a subsequent baking step at about 600 °C in air. The phosphor must be able to withstand this "lehring" process.

Often a protective coating is applied to the glass bulb prior to the application of the phosphor layer. This protective layer consists of a highly refractive material such as alumina. Its primary function is the protection of the glass against discoloration by the discharge, resulting in an improved lumen maintenance of the lamp during life. By tuning the size of the alumina particles to the emission wavelength of the mercury discharge, the UV-reflectivity of the precoat layer can be enhanced. With the aid of such a reflective precoat the phosphor coating weight can be reduced considerably without affecting the output of the lamp.

6. Special Lamp Materials

6.1. Getters

As discussed in Section 4.1, long lifetimes and maintenance of the required lamp properties can only be obtained by controlling the chemistry of gaseous impurities. Impurities mainly consist of water, hydrogen, oxygen, nitrogen, carbon dioxide, methane, and other hydrocarbons. The source of these species may be residual gas remaining after pumping or contaminated lamp components. Lamps always contain impurities which are adsorbed at or dissolved in their solid components (e.g., water in glass). During burning, many of these impurities are gradually released into the gaseous phase. Although the total quantity of gaseous impurities may be very small ($< 10^{-6}$ mol) the effects on lamps can be severe. Notorious examples are:

1) Water vapor in incandescent lamps (cf. Section 4.2)
2) Hydrogen in gas discharge lamps, which increases ignition and reignition voltages
3) Oxygen-containing gases, which may corrode electrodes and filaments
4) Residual gases in vacuum incandescent lamps or outer bulbs, which cause arcing and may reduce thermal insulation

Lamp production processes are designed to reduce the level of impurities to a minimum within the limits of mass production. Production rates vary from 1000 to 6000 lamps per hour and the time available for pumping and degassing is about 1 min per lamp. However, slow degassing reactions (e.g., desorption of water from quartz) take hours. In most lamps this problem is overcome by using a getter. A getter can be regarded as a chemical pump that is built into the lamp and can absorb harmful impurities. The getters ensure that the proper gas composition is obtained and maintained during lamp life. Three types of getters are used:

1) Evaporation getters in which the getter is activated by fast evaporation and/or thermal decomposition (P_4, P_3N_5, TiP, Ba, $Ba + Pt/Al_2O_3$)
2) Zirconium-based getters (Zr + Al, Zr – Al alloys, Zr – Ni alloys)
3) Tantalum-based getters (Ta, Ta/W)

Evaporation Getters. Red phosphorus, P_4, is the most widespread phosphorus getter for incandescent lamps. The self-combustion in air and the high vapor pressure of red phosphorus limit the maximum process temperature during lamp production to 650 K. Higher temperatures are possible with more stable phosphorus compounds, such as phosphorus pentanitride, P_3N_5.

Phosphorus getters are dosed in the lamp by dipping the filament in a suspension of fine getter powder. After pumping and sealing off, the lamps are flashed for about 1 s several times. During the first flash the phosphorus getter evaporates and precipitates at the lamp bulb. During subsequent flashes the phosphorus layer reacts with the harmful gases.

Figure 36 displays the cleanup of gases in a clear vacuum incandescent lamp by red phosphorus. After pumping the residual pressure of 1 Pa is predominantly due to nitrogen. Without phosphorus, the pressure increases upon flashing to approximately 5 Pa due to the formation of carbon monoxide from carbon impurities in the tungsten filament. In lamps with a phosphorus getter, the pressure decreases to < 0.1 Pa. This low pressure prevents arcing.

Figure 36. Pressure evolution in clear vacuum incandescent lamps during flashing without (a) and with (b) red phosphorus

The *titanium phosphide getter* works according to the same principle as phosphorus. TiP is used if higher thermal stability of the getter is required.

The *phosphorus pentanitride getter* decomposes during flashing into PN, N_2, and yellow P_2. Due to the formation of nitrogen, this getter can only be used in gas-filled incandescent lamps. The phosphorus is used to bind oxygen and water with formation of condensed phosphoric acid at bulb temperatures below 500 K. With higher bulb temperatures, a second getter (i.e., the zirconium – aluminum getter) has to be used (see below).

Barium getters are used in lamps to maintain the vacuum in the outer bulbs of low-pressure and high-pressure sodium lamps. Pressures of less than 0.1 Pa are required to prevent arcing and to ensure thermal insulation. Because of its high chemical activity, pure metallic barium cannot be used. Instead, a powder mixture of the intermetallic compound $BaAl_4$ and nickel is enclosed in a metallic ring and inserted in the outer bulb. After pumping and sealing off, the getters

are heated inductively to 1200 – 1300 K. This starts an exothermic reaction leading to the formation of a nickel – aluminum alloy in the ring and the evaporation of barium. Barium is deposited on the cold glass wall as a porous metallic film. This film reacts readily with most gases (e.g., H_2, N_2, O_2, H_2O, CO, and CO_2) apart from noble gases and methane.

After pumping off the outer bulbs of high-pressure sodium lamps, the pressure at 300 K is about 1 Pa and the residual gas composition is 70 % hydrogen and 30 % air. After deposition of the metallic barium film the pressure decreases to 0.1 Pa and more than 90 % of the gas consists of methane. Methane is formed as a byproduct when the barium film reacts with carbon-containing species and water or hydrogen. Figure 37 shows the evolution of the methane pressure in the outer bulbs of high-pressure sodium lamps. Starting at 0.1 Pa, the pressure rises to a maximum slightly below 1 Pa after 10 min. After 2 h in operation, the pressure has decreased to less than 0.1 Pa as a result of the thermal decomposition of methane at the hot discharge tube (temperatures > 1000 K).

Figure 37. Evolution of the methane pressure in the outer bulbs of high-pressure sodium lamps

Since the niobium feedthroughs of the discharge tube are permeable to hydrogen, the barium film in the outer bulb also reacts with residual hydrogen from the discharge tube. The outer bulb pressure in lamps that have burned for a few hundred hours is approximately 3×10^{-2} Pa. The gas composition is 75 % helium, 15 % argon, and 10 % methane. Helium originates from air via permeation through the outer bulb wall. Barium is being increasingly replaced by zirconium-based getters.

The residual pressures in the outer bulbs of low-pressure sodium lamps after sealing and after evaporation of barium are the same as in high-pressure sodium lamps. Since the temperature of the discharge tube is about 550 K, methane is not decomposed thermally. The presence of methane diminishes the lamp efficacy due to thermal leakage. A methane decomposition catalyst comprising highly dispersed platinum on a porous alumina pellet was introduced in the 1980s. A single catalyst pellet mounted in the lamp decomposes the methane effectively at a temperature of 500 K. The carbon precipitates in the porous alumina pellet and hydrogen is captured by the barium getter. Within 15 h the methane pressure declines to below 10^{-2} Pa as shown in Figure 38. This application ensures excellent heat insulation during the complete life of 15 000 h of low-pressure sodium lamps.

Figure 38. Evolution of the methane pressure in the outer bulbs of low-pressure sodium lamps without (a) and with (b) a decomposition catalyst (0.5 % Pt, Al_2O_3)

Zirconium-Based Getters. Zirconium has a very high chemical affinity for oxygen and nitrogen and also forms stable hydrides. At 600 – 650 K the changes in free energy for binding oxygen, nitrogen, and hydrogen are approximately 1000, 600, and 100 kJ/mol, respectively. However, surface layers of oxides and nitrides impede the absorption of hydrogen. At temperatures above 600 K, a metallic zirconium surface is formed because the surface oxide and nitride layers dissolve in the bulk zirconium. Conse-

quently, zirconium does not take up hydrogen below approximately 600 K.

In *gas-filled incandescent lamps,* a getter suspension comprising an 80 : 20 wt % mixture of zirconium and aluminum powder is applied at the stem or the lead wires. The temperature of the getter in an operating lamp is about 700 K and hydrogen is therefore absorbed. Hydrogen comes from water, which is always present in the bulb wall or its coating. As the wall temperature rises the water is released and consequently the water vapor cycle starts (cf. Section 4.2). Without the zirconium – aluminum getter, lamps with a designed life of 1000 h would only burn for a few hundred hours.

The gas-filled outer bulbs of *metal halide lamps* are provided with a hydrogen getter. Water vapor desorbed from the glass wall is converted into hydrogen and metal oxides at hot metal parts inside the outer bulb. Without a getter the hydrogen pressure may reach 25 Pa depending on the quality of the degassing process and the bulb temperature. After a few hundred hours the hydrogen pressure inside the discharge tube also increases because of a slow permeation of hydrogen through quartz. This results in increasing ignition and reignition voltages and ultimately in extinction of the lamp. To overcome these problems, the outer bulb getter has to maintain a hydrogen pressure of less than 5 Pa.

Since the gas filling consists of a mixture of noble gas and nitrogen, the getter must be selective for hydrogen. An alloy of zirconium and aluminum (84 : 16 wt %) or a zirconium – nickel compound (73 : 27 wt %) is commonly used. These getters are applied as porous pellets, rings, or coated strips. The zirconium – aluminum alloy operates in the temperature range 650 – 750 K where it is activated by prolonged exposure to hydrogen. Below 650 K the surface layer is impermeable to hydrogen and above 750 K nitrogen is gettered too. The zirconium – nickel compound absorbs hydrogen readily between 550 and 750 K. Nickel catalyzes the dissociation of hydrogen and thus facilitates hydrogen uptake. Figure 39 shows the influence of the getter on the evolution of the partial hydrogen pressure in the outer bulb of metal halide lamps. Both getters absorb the evolved hydrogen; the zirconium – nickel getter can reduce the hydrogen pressure to below 5 Pa within 10 h.

Figure 39. Partial hydrogen pressure inside the outer bulb of a high-pressure metal halide lamp as a function of the operating time of the lamp
a) Without a getter; b) With a Zr – Al getter at 350 °C; c) With a Zr – Ni getter at 250 °C

The zirconium – aluminum alloy is also used as a vacuum getter in evacuated outer bulbs of *high-pressure sodium lamps*. It either has to be activated by heat treatment (30 s at 1 200 K) or located at a position in the lamp where the temperature lies between 750 and 850 K. In contrast to the evaporated barium film, the activated zirconium – aluminum alloy does not block light transmission. This is particularly important for small lamps. The barium film, however, eliminates impurities much faster than the activated zirconium – aluminum getter.

Tantalum-Based Getters. Tantalum foil or tantalum – tungsten wire is sometimes used to getter oxygen in halogen incandescent lamps.

6.2. Amalgams [11]

Amalgams are employed in high-pressure sodium lamps and in fluorescent lamps. In high-pressure sodium lamps sodium amalgams are

used; the vaporized sodium determines the basic features of the discharge.

An interesting amalgam with "retrograde vaporization" properties is used in fluorescent lamps in which an optimum mercury vapor pressure (typically 0.5 – 1 Pa) must be maintained. Values outside this range lead to a significant decrease in light output. Usually, an excess of mercury is introduced into the lamp and thus the vapor pressure is determined by the coolest part of the tube. Fluorescent lamps are designed to operate at a temperature of ca. 40 °C. However, in certain situations the coolest part of the tube is far in excess of this. This is especially true for compact fluorescent lamps with integral control devices (see Fig. 18). By using an amalgam rather than mercury alone, the required mercury vapor pressure can be obtained at a higher wall temperature.

Figure 40. The mercury vapor pressure above pure mercury and above an Bi – In – Hg amalgam
The shaded area denotes the mercury vapor pressure range for optimal luminous flux ($\geq 90\,\%$ maximum value).

Figure 40 shows the vapor pressure of pure mercury as a function of temperature and also the mercury vapor pressure above a typical amalgam, namely Bi – In – Hg. Up to T_1 the amalgam is solid, between T_1 and T_2 the solid and liquid phases coexist, and above T_2 there is only the liquid phase. Between T_1 and T_2 the mercury vapor pressure is stabilized to a significant degree. This is because the mercury content of the liquid that coexists with the solid decreases with increasing temperature. This behavior counteracts the normal tendency of increasing mercury vapor pressure with increasing temperature.

Other amalgams, such as Pb – Bi – Sn – Hg and Pb – In – Sn – Hg are also in use, depending on the thermal balance of the lamp system.

6.3. Emitters

General. Most discharge lamps are equipped with electrodes coated with an emitter material, whose function is to improve the electron-emitting properties of the electrodes.

In gas-discharge lamps, current is mainly carried by thermionically emitted electrons. The number of electrons that can be emitted per unit time depends exponentially on the thermionic work function divided by the absolute temperature (Richardson's equation). Tungsten, which is commonly used as electrode material, has a relatively high work function. However, by using an emitter the work function can be reduced considerably, resulting in a much lower electrode temperature, which is beneficial for both lamp life and efficacy.

A common characteristic of emitter materials is that they contain one or more heavy elements of groups 1 and 2 (such as cesium and barium) or thorium. The emitters applied in gas discharge lamps usually contain barium, either in the form of barium oxide or barium-containing salts. The coverage of tungsten with a barium layer lowers the work function from approximately 4.5 eV to ca. 1.8 eV.

Emitters in Low-Pressure Discharge Lamps. The emitters used in fluorescent lamps and low-pressure sodium lamps consist of a mixture of calcium, strontium, and barium oxides. Since the oxides are not stable in air (they react with water and carbon dioxide), they are applied to the electrodes as their carbonates from a suspension. In order to obtain sufficient emitter material on the electrode, the electrode is built up from a main wire coiled with a thinner wire (Fig. 41). The space between the wires is filled with the suspension by dipping. If an extremely large amount of emitter is required, as in low-pressure sodium lamps, the emitter is applied by cataphoresis.

Figure 41. Electrode of an operating fluorescent lamp

Conversion of the carbonates to oxides takes place during the processing of the lamp by passing a current through the electrode to raise its temperature to approximately 1200 °C. During this activation process, a second important step takes place, which implies the formation of barium, by reactions of the type:

$$6\,BaO + W \longrightarrow Ba_3WO_6 + 3\,Ba$$

The role of barium is essential, it is the real emitter in the electron-emitting systems tungsten – barium and BaO – Ba. Furthermore, barium penetrates BaO making it an *n*-type semiconductor. During lamp operation the emitter mix is depleted from the coil, which finally gives rise to the end of life of the lamp.

Emitters in High-Pressure Discharge Lamps. The electrode temperatures in high-pressure discharge lamps are much higher than those in low-pressure discharge lamps; typical values are 1800 – 2000 K and 1500 K, respectively. A mixture of calcium, strontium, and barium oxides cannot be employed due to the high evaporation rate. Instead, barium salts (e.g., tungstates) are used, which have a sufficient Ba/BaO partial pressure for proper functioning of the electrode at these temperatures.

The electrodes in high-pressure mercury and high-pressure sodium discharge lamps consist generally of tungsten rod, coiled with a thinner tungsten wire. The space between the rod and the wire is filled with the emitter material (Fig. 42). Processing of the electrode – emitter combination takes place prior to lamp processing. To get the emitter material (e.g., compounds such as $Ba_3Y_2WO_9$ or Ba_2CaWO_6) into the electrode spaces, a suspension of the tungstates is used. After application of the suspension, the electrodes are heated to remove solvent and binder, and to ensure good fixation of the emitter material to the tungsten. Tantalates, aluminates, and other tungstates or mixtures can also be used as emitter material.

Figure 42. Electrode of an operating high-pressure mercury lamp

The performance of the emitter material depends more on processing than on the choice of the material. Suspension composition and heat

treatment strongly influence the performance of the emitter.

In metal halide lamps none of the abovementioned materials can be used because the halides react with barium oxide to form the volatile oxide halides. In these lamps thoriated tungsten is sometimes used and thorium serves as the emitter. For environmental reasons, there is a trend to eliminate the radioactive thorium in lamps.

6.4. Cements and Marking Paints

Capping Cements. The function of a cement is to attach the metal cap to the glass bulb and guarantee sufficient strength of the joint until the end of lamp life under a variety of atmospheric conditions. A suitable cement must have perfect adherence to cap metals and glasses, some permanent plasticity, and sufficient resistance to moisture and elevated temperatures.

A cement composition consists of adhesives, fillers, and additives. A typical thermosetting adhesive mixture consists of shellac and phenol – formaldehyde resin. Limestone is often used as a filler. Typical additives are colophony (rosin) and silicone resin. Filler and additives are added to obtain the required rheological properties. Silicone resin also improves resistance to atmospheric influences. The cement paste is obtained by mixing the resin – cement powder with low-boiling organic solvents (alcohols).

Marking Paints. Lamp brands, type designations, etc., are applied by means of an indelible marking paint. A typical marking paint is a lead borate glass combined with silver oxide. This mixture can be applied during lamp production and then heated under reducing conditions. Other marking paints are in use (pigmented stoving enamels).

7. Coatings

The radiant flux from the envelope of a light source often requires some modification with respect to spectral distribution or spatial distribution of the light. Such modifications are effected by inner or outer coatings on the lamp envelope.

Modification of the spectral distribution may involve improvement of the color balance of the lamp, an increase of the luminous efficacy, or the filtering of unwanted radiation. The two latter aspects are especially important for lamps in which a substantial part of the radiation is in the IR region rather than in the visible region. Thin film optical filters are used for this [12]; the most common types are interference filters and semiconductor filters.

Diffusive and reflective coatings modify the spatial light distribution. In addition, they may change the color appearance. Furthermore, important examples of coatings are the fluorescent powders, discussed in Section 5.4.

Interference Filters. The properties of an interference filter are determined by the thickness and the refractive index of different films which are deposited on top of one another. By varying the number and thicknesses of the layers, an infinite number of reflection spectra can be made. Generally, only two materials are used, one with a high refractive index (e.g., titanium dioxide, tantalum pentoxide, and zinc sulfide) and the other with a low refractive index (e.g., silicon dioxide and magnesium fluoride), which are stacked alternately. The filters can be deposited on a substrate by evaporation, sputtering, dipping, chemical vapor deposition, or plasma chemical vapor deposition (→ Thin Films). The performance of the filters depends strongly on the interplay between the materials used, the deposition technique, the geometry of the substrate, and the working environment (temperature and humidity).

An example of commercially available lamps with a dielectric multilayer film is an incandescent lamp provided with a ”cold” or cold-light” mirror. The inner side of a glass ellipsoid or paraboloid is coated with the cold-light filter and the light source is placed inside the reflector. The filter reflects visible radiation to illuminate an object that has to be protected from heat, and transmits the IR radiation to another site. A typical reflection spectrum of such a dichroic filter is shown in Figure 43. The amount of heat reduction depends strongly on the geometry of the system.

Figure 43. Reflection spectrum of a dielectric multilayer film ("cold light" filter)

Another example is an incandescent lamp with a "hot" mirror on the outer lamp surface. These filters are the reverse of the "cold" mirror. Visible radiation is transmitted, while the IR radiation is reflected. This reflected IR radiation is absorbed by the filament, thus diminishing the required power input. Commercially available lamps have an energy saving around 30 %. In addition, interference films can be used to make precise adjustments to the color appearance of the lamp.

Semiconductor Filters. In a semiconductor film, the refractive index can be influenced by adding free charge carriers to the material (doping). The doped semiconductor film behaves as a metal (i.e., a reflector) at long wavelengths and as a dielectric (i.e., a transparent material) at short wavelengths. By using suitable semiconductor and dope material with a properly chosen concentration of free charge carriers and film thickness, a semiconductor filter can be made which has a high transmittance in the visible part of the spectrum and a high reflectance in the infrared. The spectral characteristics are strongly dependent on the choice of the materials. Suitable combinations for IR reflection are indium oxide doped with tin (In_2O_3: Sn) and tin oxide doped with fluorine (SnO_2: F).

A semiconductor film is used as thermal insulation for the low-pressure sodium lamp which has an optimal luminous efficacy at a sodium vapor pressure of 0.4 Pa, corresponding to a temperature of 533 K. At this temperature the discharge tube radiates a large amount of energy. To save energy, the discharge tube is surrounded by an evacuated outer bulb that is provided with a doped indium oxide filter. The reflectance and transmittance spectra are shown in Figure 44. Compared to a lamp burning in free air, the luminous efficacy is approximately tripled.

Figure 44. Reflectance (R) and transmittance (T) spectra for a semiconductor film
Doping level, N/cm^3 : a) SnO_2: F, 6×10^{20} ; b) In_2O_3: Sn, 5×10^{20} ; c) In_2O_3: Sn, 13×10^{20}

Diffusive and Color Coatings. Diffusive coatings of TiO_2, SiO_2, or Al_2O_3 powders, sometimes in combination with a colorant, are applied internally in incandescent light bulbs or in outer bulbs of gas discharge lamps. These materials are often mixed with pigments to change the color appearance. The layers are applied by suspension, vapor, or electrostatic coating. These techniques are also used with (transparent) inner color coatings. Typical materials here are prussian blue, cobalt oxide (blue), and nickel titanate (yellow). External coatings mainly consist of stoving enamels that harden at elevated temperature. A wide assortment of pigments are available which are basically not different from normal industrial pigments.

Reflective Coatings. Reflective coatings consist of aluminum, silver, or aluminum – copper (gold color). These coatings are typically applied by evaporation techniques. For more durable coatings sputtering is used.

8. Lamp Production

Nowadays, more than 15×10^9 lamps are manufactured annually. High-speed machinery is often used, as in the production of fluores-

cent lamps (worldwide production: $> 2.5 \times 10^9$ lamps per year).

Figure 45. Large-scale production of fluorescent lamps

Usually the tungsten wire and coils for the electrodes and the fluorescent powders are made separately but the rest of the operation is often integrated in one plant. Glass tubing is continuously drawn from a furnace and cut to the required length. The tubes are coated on the inside with a fluorescent powder suspension and passed through an oven at a temperature close to the softening point of glass ($\approx 600\,^{\circ}$C); this burns away the organic compounds in the fluorescent powder suspension, improves powder adhesion, and eliminates all other impurities. The hot tubes, typically at 500 °C, are then automatically transferred to sealing – exhaust machines, which can produce more than 6000 lamps per hour (Fig. 45). Electrode assemblies which have been fabricated on side lines are sealed into the ends of the tube. Since the emitter on the electrode is sensitive to humidity, it is initially applied to the electrode coil in the form of a carbonate. Once the electrode assembly is sealed into the tube, the emitter is converted to oxides by controlled heating of the electrode coil. The tubes are now exhausted to remove all gas impurities. This is often carried out via a flushing technique in order to minimize the process time. After being filled with rare gas at the correct pressure (typically 400 Pa), the tubes are sealed. Often mercury is present in a sealed holder inside the lamp and this is only opened after the lamp has been sealed. This ensures accurate dosing of mercury in the lamp and minimal mercury contamination during the process. In the final stages the lamp caps are cemented onto the ends, product information is printed on the glass, and the correct functioning of the lamp is checked before it is automatically packed.

9. Economic Aspects and Uses [13]

An estimate of the world market for lamps is given in Table 7. The highest market numbers are for incandescent lamps. However, most of the artificial light in the world is generated by fluorescent lamps, because of their high luminous efficacy and their long life (cf. Table 3). The numbers in Table 7 illustrate the general growth of the lighting market. In particular there is a strong increase in the numbers for energy-efficient lamps such as compact fluorescent and high-pressure discharge lamps (HID).

Table 7. World market for lamps (in millions of lamps)

Type of lamp	1972[a]	1984[a]	1998[a]
Incandescent	4275	5285	11 700
Fluorescent	815	1200	2650
Compact fluorescent		25	420
High intensity discharges (HID)[c]	33	49	200

[a] Excluding the Peoples' Republic of China and the former Soviet Union. [b] Total world. [c] HID is a generic term for high-pressure discharge lamps.[b]

An overview of light and radiation sources related to the main application areas (indoor, outdoor, automotive, and special radiation) is given in Table 8.

Lamps often radiate in the ultraviolet (250 – 380 nm) and near infrared (760 – 2500 nm) as well as in the visible wavelength range. Some lamps can be especially designed to radiate predominately in a nonvisible wavelength range. The applications of lamps as radiation sources are diverse and include the curing of ink, paint and photoresist layers, document copying, photochemical processes, elimination of pollution via photooxidation, and heating (→ Photochemistry). Medical applications include the treatment of skin diseases, high bilirubin levels in babies, and sterilization. The cosmetic use of radiation sources for skin tanning is well known. In horticulture and agriculture they are used to promote photosynthesis in greenhouses, to help with stock raising, and in fishing, especially in fish farms.

1. Introduction

Without the invention of the laser (→ Lasers) and the exploitation of its fascinating properties, modern society would be inconceivable. Today laser devices are indispensable in worldwide data transfer, entertainment electronics, medicine, technology, the sciences, etc. Besides the optical resonator, the heart of the laser is the light-amplifying or active medium. Suitable active media are all quantum mechanical systems in which a higher energetic level can be more highly populated than a lower level. Dye molecules occupy an important position among the different families of active media for a number of reasons that are related to their photochemical and photophysical properties. The dye laser is a remarkable and highly versatile source of tunable coherent radiation. Its success and importance are demonstrated by its wide applicability. From basic sciences, such as physics and spectroscopy, to medicine and industry, the dye laser has proved to be an extremely flexible and useful tool. The spectral range of dye laser radiation extends from the UV (300 nm) [81] to the NIR (1800 nm) [82]. Single laser dyes have tuning ranges of up to 100 nm. Dye laser radiation is created in active volumes of 10^{-15} to 1 L. Pulse energies on the order of 1 kJ, ultrashort pulse lengths in the femtosecond range and terawatt peak power, average powers of 2 kW, and conversion efficiencies higher than 80 % can be attained. In focused dye laser beams, electrical fields comparable to interatomic strength have been produced. For detailed information, see the general references.

1.1. History

The first *stimulated emission of radiation* in solution was observed by SOROKIN and LANKARD in 1966 with an alcoholic solution of aluminum chloro phthalocyanine [*14154-42-8*], stimulated by a ruby laser [11]. Independently, SCHÄFER, SCHMIDT, and VOLZE found, in the same year, that cyanine dyes were suitable for generation of laser light [12]. One year later, both groups demonstrated that a flash lamp was a suitable light source for pumping a dye laser [13]. A significant advance in the generation of narrow-bandwidth laser light was made in 1967 by SOFFER and MCFARLAND with the introduction of the reflex grating as a frequency-selective device [14]. In 1969, SNAVELY and SCHÄFER showed that the increasing population of the dye in the triplet state, which interferes with laser emission, occurs to only a limited extent in the presence of oxygen [15]. This result was the precondition for the development of the continuous dye laser, which was realized in 1970 by PETERSON, TUCCIO, and SNAVELY in the laboratories of Eastman Kodak [16]. An argon ion laser was used to stimulate a solution of Rhodamine 6 G. In the late 1980s THIEL et al. showed that continuous dye laser action can be excited by pumping with a commercial 10-mW HeNe laser [83] and – as was desired since the early days of

10.1002/14356007.a15_151

continuous dye lasers – by pumping with a specially designed noncoherent Xe arc lamp [84]. The development of continuous dye lasers led to the generation of ultrashort laser pulses of 10–30 ps (10^{-12} s), which in 1972 were shortened to 1.5 ps by Dienes [17].

In 1973, Drexhage obtained a significant increase in the efficiency of dye lasers by restricting the possibilities of the dye to undergo radiationless deactivation; this was achieved by using ring closure to increase the rigidity of the molecule [18].

1.2. Dye Laser Operation

Laser Dyes. The properties of laser dyes can be discussed on the basis of the Jablonski energy state diagram [85] (Fig. 1) which is usually accepted for the characterization of organic dyes. The singlet states S_0, S_1, S_2, etc. and triplet states T_1, T_2, etc. of a dye are broad, almost continuous bands because of the large number of vibrational and rotational states and due to interaction with molecules embedding the laser dye. The states S_2, S_3, ... and T_2, T_3, ... are summarized as S_n and T_n. In equilibrium at room temperature only the S_0 state is occupied. The population of the vibrational and rotational sublevels of the S_0 state is given by the Boltzmann distribution.

The dye molecules can be promoted into vibrational and rotational levels of excited electronic singlet states ($S_0 \rightarrow S_1$ or $S_0 \rightarrow S_n$ transition), by absorption of light. A typical absorption spectrum is shown in Figure 2. The excess vibrational energy and the energy difference between S_n and S_1 are given up on a picosecond timescale. The lifetime of the most laser dyes in S_1 state is on the nanosecond timescale. From the S_1 state, several processes can occur. The S_1 state can be deactivated to the ground state by emission of a fluorescence photon or by nonradiative internal conversion. For all UV and VIS laser dyes the quantum yield for fluorescence is quite high ($> 50\,\%$). The fluorescence quantum yield decreases with increasing laser wavelength and reaches 10^{-4} for dyes emitting above 1500 nm [82]. With a low probability, dye molecules can reach the T_1 state. The lifetime of molecules in the T_1 state is relatively long (microseconds to seconds) because the transition to the ground state (phosphorescence) is spin-forbidden.

In comparison to the vibration period the lifetimes of the S_1 and T_1 states are much longer. Hence, in these excited states a thermal equilibrium is reached. In a certain sense one the absorption of light can be regarded as the formation of a new molecule. This holds for the geometrical, dielectrical, optical, and chemical properties of the excited state. The energy of the absorbed light quantum (visible or UV) is comparable to the chemical bonding energy. Therefore the properties of the excited molecule differ strongly from those of the ground state.

For the laser efficiency the properties of the excited molecule are of decisive importance. By means of stimulated emission, molecules in the S_1 state can act as light amplifiers, a prerequisite for the lasing process (see Fig. 1). However, it has been assumed since the very beginning of dye lasers that molecules in the S_1 and T_1 states may disturb or prevent laser action due to their absorption properties. Here the absorption mainly of laser light but also of pump light must be taken into account.

Even very low absorption cross sections of the S_1 or T_1 state can reduce the laser efficiency. Consequently for efficient laser dyes in particular, the excited state properties are difficult to measure. The performance of the classical photolysis techniques is insufficient for investigating the excited dye molecules with the required precision. During the first 25 years after the invention of the dye laser, published information on the physical and chemical properties of the first excited singlet and triplet states of laser dyes was scarce and controversial. Consequently, dyes were selected by trial and error. In the early 1990s, a laser-scanning spectroscopic technique was developed [86] with which the molecular parameters important for dye laser action were measured for a number of laser dyes with high precision [87]. It turned out that the spin-allowed $S_1 \rightarrow S_n$ and $T_1 \rightarrow T_n$ absorptions are the reason for the fact that of the thousands of known dye structures, only very few molecules are efficient laser dyes or even laser active. In fact for the most efficient laser dyes the main $S_1 \rightarrow S_n$ and $T_1 \rightarrow T_n$ absorption band lies outside the spectral region of the main $S_0 \rightarrow S_1$ absorption or fluorescence.

Figure 1. Extended energy level diagram
Processes which disturb lasing: excited state absorption, re-absorption and absorption of photoproducts
Processes that do not necessarily disturb the lasing process: intersystem crossing, photoreactions from S_1 and T_1 states

Besides the properties of the excited molecules, the absorption of the remaining ground-state molecules are of interest. These molecules can disturb the laser process by absorption (so-called re-absorption) of the created laser light. The importance of this process decreases with increasing narrowness of the ground state absorption band and increasing magnitude of the Stokes shift. Disturbances caused by re-absorption also can be reduced by using a lower dye concentration. However this again leads to less efficient absorption of the pump light. To absorb the pump light even at low dye concentrations, multichromophore dyes are used. In these dyes additional pump light absorbers (antennas) are covalently bound to the laser chromophore. The chromphores are separated by mesomeric structures. After the antennas are excited, the laser chromophore is excited by Förster energy transfer. It was shown that the laser efficiency of multichromophore dyes is generally reduced by a compulsive appearance of excited state absorption caused by the antennas [88].

To classify the importance of the dye properties discussed above, it is useful to distinguish between short- and long-pulse pumped dye lasers. When the temporal profile of the pump intensity is much shorter than the triplet lifetime, the triplet state absorption is of less importance. Hence, by applying a sufficient pump intensity the efficiency of the active medium is exclusively determined by the competition between stimulated emission and $S_1 \rightarrow S_n$ absorption. In practice, for good laser dyes at the maximum of the tuning range, the $S_1 \rightarrow S_n$ absorption reduces the lasing efficiency by $1-10\,\%$. At shorter wavelengths the tuning range is generally limited by re-absorption [89]. If the temporal profile of the pump intensity is comparable to or even longer than the triplet lifetime, then, besides the $S_1 \rightarrow S_n$ absorption, the population (accumulation) of molecules in the T_1 state will be of particular interest. Molecules in the T_1 state are removed from the pump–lasering cycle. These molecules can be compensated by an increased dye concentration. Therefore, this process does not disturb the laser process noticeably. However, molecules in the T_1 state may absorb pump or laser light and thus reduce laser efficiency or prevent lasing altogether. This disturbance can be reduced by decreasing the triplet state population. In all liquid solutions used as active dye laser media, the triplet state lifetime is determined by intermolecular quenching with dissolved molecular oxygen [90]. With the exception of the solvent ethylene glycol, which is used in continuous-wave dye lasers, the triplet lifetime in air-saturated solvents that are used in dye lasers is limited to values of less than 1 μs. A further reduction in the triplet lifetime has been achieved by using additional triplet quenchers, for example, unsaturated hydrocarbons such as cycloheptatriene or cyclooctatetraene as well as 2,2,6,6-tetramethylpiperidine or (+)-(*S*)-1-(9-anthryl)-2,2,2-trifluorethanol [90], [21], [22]. Lüttke et al. combined a laser dye with a triplet quencher

that is covalently bound to the dye but mesomerically isolated. The resulting quenching effect is quite pronounced when the connecting link between the fluorescent oxazole compound and *trans*-stilbene is a CH_2 group [23]. The organic quenchers tend to be unpleasant and difficult to use. So far in practice these agents are of minor importance.

In most continuous-wave dye laser systems, ethylene glycol is used as solvent. Owing to its high viscosity and its low oxygen solubility the triplet lifetime in this solvent is generally longer than 5 μs. Under these conditions even rhodamine 6G, the most popular and one of the most efficient laser dyes is laser inactive [91]. Only fast removal of the dye molecules in the triplet state will make laser action possible. This is achieved by using a fast-moving dye solution (jet technique).

Photodecomposition. The chemical properties of excited dye molecules are assumed to differ from those of the ground-state molecules. Given the intense excitation in the laser, intermolecular chemical reactions between dye molecules in the S_1 and T_1 states and reactants are of twofold interest. First, the excitation photon which initiates the photoreaction is lost to the laser process, and the photoproducts may absorb pump or laser light. Both processes reduce the laser efficiency, even that of a new laser solution. Second, possible irreversible photoreactions also lead to photodegradation and therefore to a light aging of the active medium. Radicals and singlet molecular oxygen are frequently discussed as reactants. To date, published information concerning the nature of the photodecomposition even of frequently used laser dyes is scarce and controversial. A review is given in [92]. In practical applications, the durability of the laser medium seems to be mainly determined by small amounts of impurities present in the dye or the solvent. It is generally absorption at the laser wavelength rather than the loss of dye that has the major degrading effect on laser output. In some cases the addition of agents (ascorbic acid, triplet quenchers, radical interceptors, etc.) or the removal of oxygen stabilizes the dye solution. So far in practice this technique is of minor importance.

Dye Laser Media. Besides the laser dye itself, the matrix which embeds the laser dye is of major importance not only for laser efficiency but also for the durability of the laser medium and the beam quality. In most dye laser devices the laser dye is dissolved in liquid solvents like ethanol, methanol, dimethyl sulfoxide, ethylene glycol, water, etc. or mixtures thereof. As discussed above the viscosity and the oxygen solubility of the solvent determines the triplet lifetime and to a certain extent the intersystem crossing rate constant the of the laser dye.

Water is a particularly suitable solvent for dye lasers, because at room temperature the temperature dependence of the refractive index is one order of magnitude lower than those of organic solvents. Around 0 °C the temperature dependence of the refractive index completely disappears. Hence, in water the inevitable nonuniform heating by the pump light does not lead to massive beam disturbances. A disadvantage is that many dyes form aggregates in aqueous solution. This can be prevented by the addition of surface-active compounds that can form micelles [24]. Aggregation of the dye can also be curtailed by addition of fluoroalcohols [25].

Intensive effort was devoted to impregnating organic dyes into various matrices, with the aim of achieving solid-state dye lasers [93]. Polymers, nanoporous hosts, silica gels, xerogels, alumina gels, ormosils, and composite glasses were used as matrices. Solid-state lasers have advantages over liquid dye lasers by being nonvolatile, nonflammable, nontoxic, compact, and mechanically stable. Problems such as heat dissipation and photodegradation, however, still remain to be solved for high-power applications. For long-pulse pumped and continuous-wave dye lasers an efficient triplet state quenching has also not yet been realized.

Excitation Sources. All practical applied dye lasers are pumped optically. Lasers such as Ar ion, Kr ion, nitrogen, Nd:YAG, Cu vapor, excimer, and semiconductor lasers, as well as noncoherent light sources such as Xe flash and continuous lamps are used as pump sources. Electronically pumped laser action of vaporized dye molecules is also possible [94] but has no practical relevance.

A current challenge is the electronic excitation of conducting polymers impregnated with a

laser dye. Although optical pumped laser action has already been achieved, so far no laser action could be obtained from electrically excited devices.

1.3. Uses

The dye laser is used in high-resolution spectroscopy, for example, LIF (laser-induced fluorescence), absorption, LIDAR (light detection and ranging), coherent and incoherent elastic and inelastic scattering methods, REMPI (resonance-enhanced multiphoton ionization), etc. [95]. Today these spectroscopic tools are widely used in biology, medicine, technology, fundamental science, etc. The high intensity and the narrow beam of laser radiation allow analytical measurements to be carried out on samples that are in a great distance from the measuring equipment. For example, a sodium concentration in the atmosphere at a height of 80 – 110 km of 10^9 atoms per cubic meter can be detected [27]. Similarly, one molecule of NO_2 in 10^7 molecules of air can be detected at a distance of 4 km [28].

The dye laser allows isotope separation with a high enrichment factor because of its very narrow linewidth. In a mixture of two chemically identical molecules which can be differentiated solely by isotopic composition, selective reaction of one type of molecule can be carried out if the absorption spectra, on the grounds of the isotopic shift, are so different that only one type of molecule absorbs laser light whereas the other type remains in the chemically inactive ground state. For enrichment of the isotope ^{37}Cl, iodine monochloride vapor in acetylene was excited with the continuous radiation of a Rhodamine 6 G dye laser. The selectively excited ^{37}ClI reacted with acetylene to form 1-chloro-2-iodoethylene [29]. By stepwise photochemical decomposition of symmetrical tetrazine molecules containing only ^{14}N or a mixture of ^{14}N and ^{15}N to hydrogen cyanide and nitrogen by irradiation with a dye laser (containing sodium fluorescein as active medium) pumped with an argon laser, nitrogen isotopes ^{14}N and ^{15}N could be separated [30]. Moreover, promising first attempts have been made for isotopic separation of ^{235}U and ^{238}U with a dye laser.

The ultra-short light pulses (femtosecond timescale) which can be produced by dye lasers are extensively used, for example, for the investigation of elementary chemical reactions (femtochemistry). Breaking and formation of chemical bonds have been observed in real time [96]. Nowadays, an exciting challenge is the time-resolved observation of electronic transitions. For this purpose light pulses on the attosecond time scale are necessary. Owing to the broad emission spectra of organic dyes, this aim should be reached in the near future.

Laser dyes include a large number of long-known fluorescent compounds such as Rhodamine 6 G. Other representatives are optical brighteners (→ Optical Brighteners) and fluorescent dyes (→ Fluorescent Dyes, Chap. 1.) from the large chemical companies (e.g., Bayer, CIBA-Geigy, Hoechst, Eastman Kodak). The range of laser dyes is completed by compounds that have resulted from university research. Special firms have overtaken the distribution of laser dyes: Lambda-Physik GmbH, Göttingen (Lambdachrome laser dyes); Exciton Chemical Co., Dayton, Ohio; Radiant Dyes Chemie, Wermelskirchen. An exception among the larger companies is Eastman Kodak, Rochester, New York, which offers laser dyes as Kodak Laboratory Chemicals.

2. Classes of Dyes

Since the invention of dye lasers, a considerable number of dye structures were found to be suitable for generating laser radiation. Some extensive systematic reviews are given [97–100]. Here only the most important dye classes are discussed.

A dye is generally understood to signify a compound that absorbs light in the visible region of the spectrum. The concept of laser dyes is considerably broader. The spectral range of laser emission is 300 – 1800 nm; that is, it embraces long-wavelength ultraviolet and the beginning of the infrared. The structures of the compounds used are also correspondingly diverse, their common feature being a high fluorescence quantum yield.

2.1. Polyphenyl and Heteroaromatic Compounds

The short-wavelength part of the spectrum is dominated by aromatic compounds, at least those not substituted with donor groups. Condensed aromatic ring systems, such as anthracene, pyrene, or perylene possess only moderate laser properties because of their excited-state absorption. This is not true for those systems formed by linear coupling of benzene rings.

In contrast to biphenyl *p*-terphenyl [*92-94-4*] is an efficient laser dye. When excited with a KrF excimer laser, the tuning range is 322 –352 nm. Substitution of *p*-terphenyl in the 2,2″-positions with methyl or trifluoromethyl groups leads to twisting of the terminal benzene rings about the long molecular axis as a result of steric hindrance; this produces a moderate hypsochromic shift, resulting in a tuning range of 308 – 352 nm [31].

p-Quaterphenyl [*135-70-6*] is tunable over the range 360 – 390 nm by using a nitrogen laser for excitation. Introduction of methyl groups into the terminal rings in sterically hindered positions also causes a hypsochromic shift and a reduction in intensity of the fluorescence band, again because of twisting. Excitation with an XeCl excimer laser gives a tuning range of 335 – 375 nm [32]. Substitution with a sulfonic acid group in the *p*-position of quaterphenyl renders the compound sufficiently soluble in ethylene glycol. It is commercially available as Polyphenyl 1 (**1**) (Lambda-Physik) for use in cw lasers. The tuning range attainable by stimulation with an argon ion laser is 362 – 412 nm. Polyphenyl 1 is produced by palladium-catalyzed dimerization of 4-bromobiphenyl-4′-sulfonic acid [33]:

1

Substitution of quinquephenyl with methyl or *tert*-butyl groups leads similarly to effective laser dyes which, by stimulation with an XeCl excimer laser, are tunable from 355 to 400 nm [34].

The exchange of phenyl groups for heterocyclic groups leads to a shift of the absorption band to long wavelengths. Furan 1 (**2**) (Lambda-Physik) is produced by condensation of salicylaldehyde with bis(chloromethyl)biphenyl, followed by ring closure and subsequent sulfonation:

$n = 2, 3$ **2**

When dissolved in methanol and stimulated with an XeCl excimer laser, Furan 1 can be tuned from 410 to 435 nm [35].

Another heteroaromatic polyphenyl compound is 1,4-phenylenebis(5-phenyl-2-oxazole) [*1806-34-4*] (**3**) (POPOP). By coupling of two fluorescent compounds, dimethyl-POPOP (**3a**),

3

3a

and terphenyl via the methyl group SCHÄFER and LÜTTKE obtained bifluorophoric laser dyes e.g., 1-(4-methyl-5-phenyloxazolyl-2)-4-(4-terphenylylmethyl-5-phenyloxazolyl-2)-benzene (**4**) which, through energy transfer,

enables a greater part of the excitation energy to be used [36].

4

2.2. Stilbenes

4,4′-Diphenylstilbene [*26569-48-2*] is suitable for pulse operation with an XeCl excimer laser or a nitrogen laser; the tuning range is 395 – 415 nm. Introduction of sulfonic acid groups in the *para* positions gives a laser dye that has sufficient solubility in ethylene glycol to be suitable for cw operation; stimulation with an argon ion laser gives a tuning range of 395 – 435 nm [37]. This dye is available under the name Stilbene 1 (**5**) (Lambda-Physik). Its lightfastness is strongly dependent on the mode of excitation. With cw stimulation the input energy amounts to 200 Wh measured until the output of the dye laser energy has dropped to 50 % while in case of excimer stimulation it is only 10 Wh [38]. The photokinetics of laser dyes were investigated by Gauglitz with fluorescence spectroscopy; a rapid decline in performance occurs because of *cis* – *trans* rearrangement, followed by slow decomposition of the *cis* isomer [39].

The synthesis of Stilbene 1 can be carried out by Wittig – Horner reaction of the potassium salt of 4-carboxaldehydebiphenyl-4′-sulfonic acid with 4-diethoxyphosphonomethylbiphenyl-4′-sulfonic acid ethyl ester in dimethylformamide, in the presence of potassium *tert*-butoxide, and subsequent saponification [40]:

5

Majewski and Krasinski investigated the laser activity of the optical brightener **6** derived from 4,4′-diaminostilbene-2,2′-disulfonic acid. They used only compounds which had no further sulfonic acid groups [41].

6

The brightener **6** with $R = OCH_3$ and $n = 0$ [*3426-43-5*] has a tunable range of 415 – 445 nm when stimulated with a nitrogen laser. The tuning range of the compounds **6** is increased considerably by the introduction of additional sulfonic acid groups into the phenyl substituents. The brightener with $R = N(C_2H_4OH)_2$ and $n = 1$ [*12224-02-1*] can be tuned from 417 to 464 nm [42]. Furthermore, these compounds are suitable for cw operation. The tuning range of the dye with $R = N(C_2H_4OH)_2$ and $n = 1$ is 410 – 480 nm [43].

Distyrylbiphenylsulfonic acids constitute a particularly useful class of laser dyes [44]. The laser dye Stilbene 3 (**7**) (Lambda-Physik) in methanol solution can be tuned over the ranges 412 – 443 nm and 408 – 457 nm by using an XeCl excimer laser and a nitrogen laser, respectively. In aqueous solution, the tuning curve is shifted to long wavelength, reaching 420 – 470 nm. Addition of a nonionic surfactant increases the laser performance by deaggregation [45]. Stilbene 3 (**7**) [*27344-41-8*] is particularly suitable for use in cw dye lasers.

7

Stimulation with an argon ion laser gives a particularly broad tuning range of 403 – 493 nm

[43]; its lightfastness is strongly dependent on the mode of excitation. With cw stimulation the input energy amounts to 300 Wh measured until the output of the dye laser energy has dropped to 50 % while in case of excimer stimulation it is only 14 Wh [38].

2.3. Coumarins

A large number of highly effective laser dyes can be found among the coumarins. Their tuning range is 400 – 600 nm; with specific substitution this can reach 700 nm. Most coumarin laser dyes contain an amino group in the 7-position. 7-Hydroxycoumarins have also been described as laser dyes.

4-Methyl-7-hydroxycoumarin [*90-33-5*] in alkaline solution can be tuned from 420 to 520 nm by excitation with a flash lamp [46]. With a nitrogen laser, the tuning range is 370 – 580 nm; with continuous stimulation by an argon ion laser, it is 460 – 560 nm. This unusually broad tuning range results from the large number of possible mesomeric structures, including (**8a**, **8b**, and **8c**):

8a **8b**

8c

Laser activity can also be observed in strongly acidic solution, due to the pyrylium structure **8c** [47]. The enolate anion at the 7-position of coumarin may also be replaced by the phenylsulfonylamino group [48].

The oldest aminocoumarin dye is 7-dimethylamino-4-methylcoumarin (**9**), which VON PECHMANN obtained by condensation of 3-dimethylaminophenol with ethyl acetoacetate in the presence of zinc chloride [49]:

9

This compound is available as Coumarin 311 (Kodak) [46]. The parent compound 7-amino-4-methylcoumarin [*26093-31-2*] is available as Coumarin 120 (Kodak). This dye is tunable over 423 – 462 nm by stimulation with an XeCl excimer laser, and over 425 – 475 nm by continuous stimulation with an argon ion laser. The tuning range of 7-diethylamino-4-methylcoumarin [*91-44-1*] (Coumarin 1, Kodak) is 436 – 486 nm (nitrogen laser stimulation) and 450 – 500 nm (continuous stimulation with an argon ion laser). A disadvantage of this laser dye is the low photostability. Particularly when a flash lamp is used for excitation, the 4-methyl group undergoes photochemical oxidation to a carboxyl group. Even a small amount of photooxidation product can reduce the laser radiation because the absorption wavelength of the carboxylic acid derivative lies within the range of the laser wavelength of the 4-methyl compound. SCHIMITSCHEK was able to raise the photostability of coumarin compounds considerably by introduction of the CF_3 group in place of CH_3 [50]. 7-Dimethylamino-4-trifluoromethylcoumarin [*53518-14-2*] (Coumarin 152, Kodak) has a tuning range of 490 – 570 nm by stimulation with a XeCl excimer laser.

The sodium salt of 4-methyl-7-sulfomethylaminocoumarin (Coumarin 175, Kodak) is water-soluble and thus insensitive to formation of optical inhomogeneities when a flash lamp is used for excitation [51].

An increase in fluorescence quantum yield can be obtained by limiting the opportunities for radiationless deactivation. In Coumarin 1, loss in energy results from rotation of the diethylamino group; this rotation is cut off by ring closure with the phenyl group. This effect was called "rigidizing" by DREXHAGE. Using 3-

Table 1. Tuning ranges of some coumarin laser dyes

[a] cw Krypton laser.

hydroxyjulolidine, he produced a large number of highly effective coumarin laser dyes, including Coumarin 102 and Coumarin 153 (Kodak, Lambda-Physik) (see Table 1) [52].

Introduction of an N-heterocyclic group in the 3-position of the coumarin system shifts the tuning range of 7-aminocoumarin compounds to longer wavelengths. These dyes were first produced in 1958 for dyeing textiles (→ Methine Dyes and Pigments). Coumarin 6 (**10**, Kodak, Lambda-Physik) is obtained by reaction of 2-hydroxy-4-diethylaminobenzaldehyde with 2-cyanomethylbenzothiazole in alcohol by using piperidine as catalyst [53] (see also Table 1):

10

DREXHAGE et al. produced a continuous emission with coumarin 6 by dissolving it in aqueous solution by adding *N,N*-dimethyldodecylamine *N*-oxide, with cyclooctatetraene as triplet quencher, and using an argon ion laser for stimulation [54]. Coumarin 7 and Coumarin 30 contain the benzimidazolyl group in the 3-position of the coumarin (see Table 1).

Other efficient laser dyes have a benzoxazolyl group in the 3-position [55]. A cyano group can be substituted in the 4-position of these dyes by addition of sodium cyanide and subsequent oxidation with bromine [56]. By this means, the tuning range of coumarin dyes can be extended to 705 nm [57], e.g., RDC 650 (Radiant Dyes Chemie) (see Table 1).

Azacoumarin laser dyes (e.g., **11** [*57980-06-0*]) are obtained by treatment of 2-hydroxy-6-dialkylaminopyridine with acetoacetates [58]:

11

Rhodamine 630			595 – 680 [36]	595 – 660 [37]	595 – 680 [38]
Sulforhodamine B	[*2609-88-3*]		594 – 642		610 – 680

[a] With N_2 laser. [b] cw Krypton laser.

Table 3. (Continued)

Dye	CAS registry number	Structure	Tuning range, nm		
			XeCl Excimer	Flash lamp	cw Argon
Sulforhodamine 101	[*60311-02-6*]		616 – 667		636 – 675
Rhodamine 700	[*63561-41-1*]		701 – 768	705 – 798	700 – 810 [b]

[a] With N_2 laser. [b] cw Krypton laser.

Further effective laser dyes are found in the range of the carbostyril compounds (see Table 2). By analogy to coumarins, they are obtained by reaction of 1,3-diaminobenzene and its alkyl derivatives with ethyl acetoacetate [59].

Chinolon 390 (**12**) is an aza analogue of the carbostyril dyes, prepared by treatment of 2,6-diaminopyridine with malonic ester and subsequent alkylation [60]:

12

Nd-YAG 3rd 380 – 400 nm

2.4. Xanthene Dyes

Xanthene dyes result from insertion of an oxygen bridge in triphenylmethane dyes (→ Triarylmethane and Diarylmethane Dyes, Chap. 6.). In this way, the rotation of phenyl groups is hindered and the possibilities of radiationless deactivation are restricted. These dyes show strong fluorescence and were discovered relatively early as laser dyes (see Table 3). A ruby laser was originally used for stimulation, followed by a flash lamp, the latter is characterized by a steep increase in energy. The preferred dyes are sodium fluorescein and Rhodamine 6G (see Table 3) [61]. From the early days of dye lasers until the early 1990s, Rhodamine 6G remained the universally applicable laser dye with the highest performance. Today, only very few dyes (Rhodamine 630, see Table 3; Pyrromethene 597, see Section 2.6) reach a slightly higher laser efficiency in some laser systems.

13

A mixture of two laser dyes can lead to an increase in radiation intensity. This is the case, for example, with a 1 : 1 mixture of Rhodamine B and Rhodamine 6 G [61].

The fluorescence quantum yield of Rhodamine B is temperature-dependent: at room temperature, it is ca. 40 %, and it can be increased to almost 100 % by reducing the temperature; in contrast, at the boiling point of ethanol it is only a few percent. This is an example of radiationless deactivation by thermal stimulation [62]. Coupling the two alkyl groups with the aromatic ring, e.g., in Rhodamine 101, strongly reduces the mobility of the amino group; the fluorescence quantum yield then reaches almost 100 % at room temperature [52] (see also Table 3).

Conversion of 3,6-dichloro-9-phenylxanthylium-2′-sulfonate with taurine [*107-35-7*] in aqueous solution leads to Rhodamine 504 (**13**, Radiant Dyes Chemie) whose tuning range with continuous excitation (550 – 622 nm) is shifted to shorter wavelengths compared to Rhodamine 6 G (Table 3) [63].

Sulforhodamine B [64] and Sulforhodamine 101 (Kodak) are suitable for continuous stimulation (see Table 3).

A cyanide group can be introduced into the 9-position of the xanthene ring system by addition of alkali cyanides and oxidation with bromine to give (**14**) (Rhodamine 800, Lambda-Physik, RDC 780, Radiant Dyes Chemie). The fluorescence is shifted 100 nm to longer wavelengths by this means. The absorption and fluorescence spectra of dye **14** in methanol are shown in Figure 2.

14

These dyes are characterized by a particularly broad tuning range; with a krypton ion laser, **14** can be tuned over 730 – 835 nm [65] (see Fig. 3).

A CF_3 group in the 9-position of the xanthene system produces a similar bathochromic effect. The tuning range of Rhodamine 700 (Lambda Physik) is 700 – 810 nm (see Table 3).

Table 4. Rhodamine and phyronine dyes with fixed amino groups

Dye	Structure	ϕ_{fl},[a] %	$\Delta\lambda$,[b] nm
Rhodamine 101 (acid)		93	21[c]
Rhodamine 630		97	25[c]
Pyronine 105			18[d]
KS 35		94	20[d]
Rhodamine 700 (acid)		38	26[d]
JA 47 (acid)		62	31[d]
Rhodamine 800 (acid)		19	26[c]
CNR 1 (acid)		26	33[c]

[a] Fluorescence quantum yield. [b] Stokes Shift. [c] In ethylene glycol. [d] In ethanol.

As shown in Table 3 the fixation of the amino groups by the julolidine structural motif leads to a number of efficient laser dyes. Their laser efficiency can be further increased if the amino groups are embedded in a single six-membered ring instead of the julolidine backbone [103] (Table 4). this dye class is distinguished by a higher fluorescence quantum yield and – more important for the increased laser efficiency – by reduced re-absorption [101].

2.5. Pyrromethene Dyes

Pavlopoulos and Boyer [104], [105] established pyrromethene BF_2 complexes as laser media. Phosphoric acid at 140 °C converts ethyl-3,5-dimethylpyrrole-2,4-dicarboxylate to 2,4-dimethylpyrrole. Treatment with acetyl chloride at 40 °C converts the latter to 1,3,5,7,8-pentamethylpyrromethene hydrochloride, and subsequent treatment with triethylamine and boron trifluoride etherate affords 1,3,5,7,8-pentamethylpyrromethene BF_2 complex (Pyrromethene 546).

X = H, CH_2, etc.

Table 5. Pyrromethene laser dyes

Dye	Structure	Pump source	Tuning range, nm
Pyrromethene 546		flash lamp	520 – 580
Pyrromethene 556		flash lamp/cw Ar	540 – 580/530 – 624
Pyrromethene 567		cw Ar/Nd:YAG ∗	552 – 608/549 – 592
Pyrromethene 580		flash lamp	
Pyrromethene 597		flash lamp	
Pyrromethene 650		Nd:YAG ∗	

∗ Frequency-doubled.

15

In similar manner, the Pyrromethene dyes shown in Table 5 are synthesized. These efficient and stable laser dyes [93], [100] can be used for pulsed and continuous operation.

2.6. Methine Dyes

SCHÄFER et al. irradiated a 10^{-4} M solution of dye **15** (3,3′-diethylthiatricarbocyanine bromide) in acetone with pulses from a 5-MW ruby laser and observed that the broad fluorescence band of spontaneous emission was reduced to a narrow, intense fluorescent band. This was the first observation of stimulated emission of a methine dye [12] (see Fig. 4).

The iodide salt of this dye is available commercially as DTTCI [*3071-70-3*] (Lambda Physik). Stimulation with an XeCl excimer laser gives a tuning range of 828 – 883 nm. Benzannelation of both terminal benzthiazole groups leads to a shift of the fluorescence band to longer wavelengths. The tuning range of 3,3′-diethyl-4,4′5,5′-dibenzothiacarbocyanine iodide [*23178-65-6*] is 899 – 975 nm. Further heptamethine dyes are listed in Table 6 [66].

These dyes can also give continuous radiation by stimulation with a krypton ion laser [67].

Insertion of a ring system in the polymethine chain raises the photostability of the dye considerably. A suitable intermediate is the dialdehyde **16**, which ZEMLICKA and ARNOLD obtained from reaction of cyclohexanone with phosphorus oxychloride and dimethylformamide by the Vilsmeier reaction [68]:

16

Condensation of **16** with 2,4-diphenyl-5,6-tetramethylenepyrylium perchlorate gives the infrared laser dye IR 5 [*61010-01-3*] (**17**, Lambda Physik):

16

17

Stimulation with an Nd – YAG laser allows the dye to be tuned over 1180 – 1400 nm [69]. DREXHAGE used the same aldehyde for synthesis of the laser dye IR 26 [*76871-75-5*] (**18**, Lambda Physik), tunable from 1200 to 1320 nm (Nd – YAG laser) [70]:

18

a) Absorption; b) Spontaneous emission; c) Stimulated emission

Table 6. Tuning ranges of some heptamethine (cyanine) laser dyes

Dye	CAS registry number	Structure	Tuning range, nm	
			XeCl Excimer	cw Argon
DTTCI	[*23178-65-6*]		899 – 975	
DMOTC	[*19764-95-5*]		774 – 810	745 – 790
HITCI	[*19764-96-6*]		837 – 905	815 – 920
IR 125	[*3599-32-4*]		890 – 960	

Pyrylium dyes lacking a methylene chain (Zero methine) (→ Methine Dyes and Pigments) fluoresce and can be tuned from 500 to 550 nm when stimulated with a ruby laser or a flash lamp [71]. An example is the dye **19** [2,6-bis(4-ethoxyphenyl)-4-pentyloxyphenylpyrylium perchlorate] [*47776-83-0*].
